thoracic surgery, that department would have to assume responsibility for the final diagnosis.

On the other hand, if a team of investigators performs all these tests on every patient with heart disease, is the clinician as we know him really necessary? Reliance upon tests engenders a certain habit of mind in which more confidence is felt in a figure than upon an opinion based on clinical judgment. Indeed, it has been rumoured that in certain more advanced stations the clinician has already been found to be redundant, and his place has been taken by an integrator who, by assessing the results of the investigations statistically, has been able to come to a diagnosis and decide on treatment without seeing the patient at all.

Valuation of Tests

All the masters of medicine have insisted on the importance of an accurate history. Unless the patient is carefully questioned regarding his symptoms diagnosis will suffer. We may therefore dismiss at once the notion that the clinical examination can be superseded. Should we then go to the other extreme and discard all tests, or at least all tests which cannot be performed by the clinician at the time of his examination, as being without value? The answer surely is "No"; but we should discriminate, and by using each test in its proper place avoid making them our masters.

No one should practise cardiology who has not had a thorough grounding in electrocardiography. The electrocardiograph is an instrument of precision. It has great uses but also limitations. In inexpert hands it can be quite dangerous. Hospital cardiographic departments should be entrusted only to those who have been trained in a recognized cardiac department. The same applies to the x-ray examination of the heart. The art of cardioscopy is not to be learnt in a day. Yet a correct appreciation of the size of the different chambers of the heart is almost, if not quite, as important an adjunct of the examination of cardiac patients as is electrocardiography. To these two tests I would add another—namely, the vital capacity—because so much can be gleaned from it and it takes so little time. These three should form part of the routine examination of patients with heart disease, as much as the recording of the blood pressure and the auscultation of the heart sounds.

Mackenzie had nothing but scorn for those who would "use an assistant to take an *x*-ray photograph of the heart and an electrocardiogram, and even blood pressure readings, and then sit down to study the report." Not much, in fact, is gained by taking an electrocardiogram, or the blood pressure oneself, but the remainder should not be left to subordinates. If one would not accept the findings of another on auscultation, it is difficult to see why his findings on cardioscopy should not usually require verification.

Tests of the speed of the circulation require no apparatus and take little time. They are available to anyone who desires to use them. But the information they give is often disappointing, and it is doubtful if they are worth including in a routine examination.

Accurate measurements of the venous pressure are helpful in many ways both in the progress of cardiac failure and in assessing the results of treatment. When the apparatus with a fine needle is generally available, venous pressure measurements will probably be included in the examination of patients with heart failure.

The exploratory work on angiography has so far been done mainly by cardiologists, but the problems concerned are almost entirely radiological. A series of rapid exposures have to be made with sufficient penetration to visualize the course of diodone as it passes through the heart. Probably as time goes on, the technique will fall more and more to the field of the radiologist, and cardiologists will call for the additional information in appropriate cases. Angiocardiography will then have to be made available in all hospitals where a cardiac clinic is established.

It is a remarkable fact that when surgeons invade a province hitherto considered to be purely medical, diagnosis almost always becomes more exact. Not so long ago the diagnosis of congenital morbus cordis was considered quite adequate by paediatricians. It is true that the development of cardiac radiology directed the attention of cardiologists to the congenital lesions years before any operative intervention was considered feasible, and many types, such as the tetralogy of Fallot, valvula pulmonary stenosis, atrial septal defect, coarctation, and the patent ductus, were recognized clinically. But the advent of thoracic surgery, and especially of the Blalock-Taussig operation, has opened a new field, and now pulmonary atresia, tricuspid atresia, and major and minor degrees of transposition are distinguished. For this angiocardiography and cardiac catheterization are often required.

Cardiac catheterization is difficult and laborious. To obtain a thorough mixing of the venous blood the catheter may need to be pushed as far as the pulmonary artery. This takes time, and there are many pitfalls, as the tip of the catheter may double back and appear in unexpected places. If the catheter passes from the right auricle to the left or from the right to the left ventricle the pressures will alter and the samples will change from venous to arterial blood. Hence the importance of the procedure in establishing the presence of septal or congenital heart disease. Otherwise it is useful only, owing to the possibility of observing directly the changes in pressure of the different chambers of the heart, and changes in the cardiac output, caused by heart failure or induced by drugs. It would seem probable that cardiac catheterization will be performed only in hospitals large enough to have a thoracic surgical unit or at research centres.

Most of these tests were devised for purposes of research. They were developed at single centres, and were later adopted generally because they were found to be useful in diagnosis. Other methods are still in the stage of development. They may or may not come to have a general application. Such are the ballistocardiogram, the radiocardiogram, and the measurement of the volume of the heart.

The ballistocardiogram enables the cardiac output to be obtained without the unpleasantness of a cardiac catheter and an arterial puncture. But estimations of the output do not help much in the diagnosis and treatment of patients with heart disease. Those with "high-output failure" have also fast circulation rates, and the circulation time is an easy test to do. In ordinary congestive heart failure the output falls only a little, and estimations of the cardiac output are unlikely ever to form part of the routine investigation of such patients.

The radiocardiogram and the estimation of the volume of the heart have opened up a new approach to the problems of heart failure. They have shown that the dilated heart empties itself slowly. With the radiocardiogram the emptying time of each ventricle can be measured separately. The test is very recent, but it is certainly important, and we may expect to hear more of it in the future.

TABLE II.—*Aetiology of Cases following Pneumothorax Treat. (54 Cases)*

12 cases followed acute reaction immediately after closed intrapleural pneumolysis
8 cases followed cavity rupture
2 cases followed spontaneous pneumothorax (suspected cavity rupture)
2 cases followed open intrapleural pneumolysis
4 cases related stenosis main bronchus, proved by bronchoscopy
3 cases related atelectasis without proved stenosis
23 cases in or following uncomplicated pneumothorax
Secondary infection occurred in 20 cases (37%).

It is to be noted that the empyema can occur not only during the course of the A.P. treatment but also after the A.P. has been abandoned as contraselective or because of persistent effusion. The case histories in this group show the onset at periods from shortly after the induction till many years after the A.P. is abandoned. An example will illustrate this.

A.P. induced in 1934, right side, for destructive disease. Effusion after six months. A.P. maintained till 1937. Then phrenic avulsion. Under medical control, well and working but with known persistent fluid. The time when the effusion became purulent is not known, but an empyema was diagnosed in 1942, eight years after the A.P. was induced, when the patient was admitted to Vardasen Sanatorium following a febrile "cold."

If a pneumothorax is abandoned because of a persistent clear effusion it is necessary to follow the progress of the effusion till it is absorbed, or, if there is no evidence that this will occur in the course of two or three months, then a surgical colleague should be consulted about future treatment.

A mixed infection alters the prognostic picture adversely. Its frequency is very high in any large series, and in the present one it is 38 out of 74 (Table III). The threat therefore hangs over every case of tuberculous empyema and the danger of secondary infection does not diminish with time in an untreated pure empyema. The following case illustrates this.

TABLE III.—*Aetiology of Secondary Infection (38 Cases)*

Known bronchial fistula	17
Acute pneumonic infection of lung with T.B. plus	7
External fistulae	5
Febrile "cold"	1
Unknown (? bronchial fistulae)	8

Case 11.—A woman had an A.P. induced in 1923 and a positive diagnosis of empyema was made in 1924. There is no information about the condition in the years that followed except that in 1939 a radiograph showed evidence of persistent pleural opacity. She was clinically well till she had an attack of bronchopneumonia in 1941, and in 1942 she developed an empyema necessitatis with stinking pus and died after drainage. This was 18 years after the known onset of a pure empyema, which was not treated.

One of the main causes of secondary infection appears to be bronchial fistula. However, not all the cases with clinically evident fistulae by any means develop clinical or bacteriological evidence of secondary infection, but the incidence of known fistulae is somewhat higher (47%) in the secondarily infected group than in the pure tuberculosis group (39%). Details of the proved fistulae are given in Table IV.

TABLE IV.—*Definite Pleurobronchial Fistulae (31 Cases)*

Diagnosis by the following means:	
Coughed-up empyema pus	9
Definite cavity rupture (radiological evidence)	8
Spontaneous pneumothorax	5
Pressure measurements	3
Contrast radiographs	3
Demonstrated at thoracoscopy	1
" open operation	1
Taste in mouth of substance injected into empyema	1

There were 14 cases of fistula among the 36 cases with no secondary infection; of these, seven followed cavity rupture and three spontaneous pneumothorax, when the fistulae were probably short-lived. Among the cases with secondary infection there were 17 fistulae.

Diagnosis of Secondary Infection.—This was made clini...ally and bacteriologically. In 33 of the 38 cases the secondary organisms were demonstrated by aerobic or anaerobic ...lture. In one the clinical condition of stinking pus ...termined the diagnosis in the absence of a positive bac...ological report, and in four it was assumed because of ...-standing open drainage of the empyema cavity at ...r operations.

Pathology

...blom's (1932) classification of tuberculous empyema, bas...n the fundamental pathology, is used in this series. He ...des the disease into four distinct pathological types: —pu...empyema without pulmonary disease (Group I); pure ...yema with pulmonary disease (Group III); mixed empye... without (Group II) and with (Group IV) pulmon... disease.

Grou... and II are less common. They comprise cases in which, fo...xample, localized empyema follows a pleurisy, or in which ...lapse treatment has been carried on for many years and ... pleural cavity has become infected but there is at the ti... of operation no tubercle bacilli in the sputum. A minimu... period of three years T.B.-negative has been arbitrarily c...en as indicating no active tuberculosis of the lungs. Colla... treatment is not needed in these groups.

Söderhjelm	112	33 (29·5%)	15 (13·4%)	3 (2·7%)	61 (54·4%)

a = Total empyema. b = Partial empyema.

Table V gives the overall results of all patients presented to a surgical department. Comparison with other published series is instructive. Jones and Alexander maintained that thoracoplasty was the standard treatment for a tuberculous empyema unless there were contraindications, while Söderhjelm (1945) is prejudiced against surgical measures because of initial unfavourable experiences, and his cases were therefore treated medically in the main.

The "cured" and "improved" cases are taken together in Table VI and the percentage of satisfactory results compared in the four groups. It will be seen that Jones and

The Time Factor

A period of six months from the estimated time of the onset of the empyema was chosen as an arbitrary dividing line, and the cases were divided into groups according to

TABLE IX.—*Time Relationship*

	No.	Cured	Improved	Died
Early cases (within 6 months)	24	16	4*	4
Late cases (after 6 months	31	12	9†	10

* 1 superficial wall fistula; 1 recent op. fistula; 1 connected bronchus.
† 3 fistulae; 1 cold abscess in wall (late)

whether or not they came to the surgeon within this time. The results are shown in Table IX; they appear to be significant, and indicate that cases should be operated upon within six months of the onset.

In the early group there are three fistulae cases among the improved cases. One was investigated by contrast radiography, and shown to have a superficial "collar-stud" abscess of the chest not related to the empyema cavity; another fistula was very small and related to a bronchial fistula, in a case operated on one year previously. The third was operated upon about eight months before.

In the late group there are three definite fistulae from the empyema cavity,* and in one patient a subcutaneous cold abscess was presumed to be related to the empyema cavity. There is therefore a somewhat higher proportion of long-standing fistulae after late operations. The number of fistulae is small compared with some other series, and a possible explanation of this lies in the use of apico...

*These three cases are among the six in which a ... not completed, but a fistula was present when last ob...

Out of 35 cases of total empyem[illegible]erated upon, an apicolysis to a larger or smaller ex[illegible] was done in 25, as this is the only mechanical mea[illegible]f collapsing the pleural space at the apex. If this is no[illegible]e there is often a very long sinus extending over the [illegible]nd medially to the mediastinal surface. The proceedu[illegible] apicolysis is, however, attended with risk, especially if [illegible]e is secondary infection.

It is clear that the longer an empyem[illegible]vity remains untreated the thicker the [illegible]ural walls beco[illegible] until at last they may be calcified and absolutely rigid. Collapse of the chest wall by a standard thoracoplasty[illegible]n fails to close the rigid cavity completely, and it is only in such late cases that the more deforming and al[illegible]angerous operations involving the opening of the chest pleural cavity are necessary, with removal of all or a[illegible]t of the stiffened tissues. In this series 10 operations of Schede and Roberts type have been performed, with th[illegible] deaths and two residual fistulae. Most of these cases[illegible]d had empyemas for several years before operation.

In this series there were four proved cases of[illegible]nosis with atelectasis and three cases of atelectasis with[illegible] any bronchoscopic evidence of stenosis. The effect on a[illegible]ogy is clear, as the lung cannot expand after pneumo[illegible]ax, and the large pleural cavity is practically certain to b[illegible]ne infected if allowed to remain: but it is also of inter[illegible]to note the effect on the extent of the operation. Of the s[illegible] cases, six had total or subtotal thoracoplasty in sev[illegible] stages and one patient died after the first stage. A br[illegible] chial stenosis is therefore an absolute contraindicati[illegible] to a pneumothorax, being attended with a high risk [illegible] subsequent empyema.

In general, also, the older the empyema the more rib[illegible] have to be removed in the standard extrapleural thoraco[illegible] plasty to close the cavity.

It is not the case, as is sometimes thought, that all operations for empyemas need to be total or subtotal thoracoplasties. Of the 55 operated cases (after excluding the four limited operations for partial empyemas) there were 17 in which seven or fewer than seven ribs had been removed at the completion of the different stages. In nine of these, only four or five ribs were removed, an operation with a negligible deforming effect. These 17 cases were again considered in relation to whether they were operated upon within six months of the onset or after this period. The results are seen in Table X.

TABLE X.—*Limited Thoracoplasties and Results as regards Empyema (17 Cases)*

	No.	Cured	Improved
Operation under 6 months	9	8	1 (early residual fluid)
Operation after 6 months	8	3	5 { 3 residual fluid; 6 years, 1 year, recent operation. 2 fistulae

In the cured cases the late result showed the lung expanded out to the chest wall below the level of the rib resections with no pleural thickening or fluid. The difference in the results in relation to time suggests that a limited operation is fully justified in early cases, but is not invariably successful in cases operated upon after six months, where a larger thoracoplasty is indicated.

If the problem is regarded from a physiological-pathological point of view it is clear that the pleura in the early stage, although infected, is still a functional membrane able to absorb the effusion if there is no reinfection and if the cavity can be obliterated as absorption proceeds.

The second of these objects can be achieved in some [illegible]ses by the physician stopping the A.P. and aiding the expansion of the lung by aspiration (if this is not prevented by a fistula, stenosis, or pleural thickening. In these cases that are dealt with early, and where the lung can be allowed to expand, the early or incipient empyema can be averted. This explains the fairly good results obtained by medical measures in Groups I and II, and also in early Group III cases.

The moderately satisfactory results obtained by conservative measures are often at the expense of the temporary collapse of the lung, usually before its re-expansion would otherwise be indicated. In some cases a cavity will still be present in the lung, and in others it may reappear when temporary collapse treatment is given up. In such cases, when the "cold abscess" of the pleura has been obliterated, it will then be necessary for the physician to refer the patient for a thoracoplasty to control the disease. Provided this is recognized, there is good ground for medical treatment of an early empyema in the first two to three months, for it is preferable to do a thoracoplasty with a closed pleural space; but there are no grounds for regarding the conservative methods of treatment as an alternative to surgery, except in those cases in which the lung does not require further collapse therapy. Delay after three months is unlikely to result in closure of the empyema cavity by conservative measures, and is disadvantageous to the patient who loses the advantage of probable cure by a limited thoracoplasty, and is exposed to the serious risk of secondary infection.

The problem of progressive exudates has had considerable light thrown upon it by the experience of Rogstad (1948) at Vardasen Sanatorium. During the years 1941–7, 1,044 A.P.s were induced in 918 patients. Of these, 169 (16%) had tuberculous effusions which were tapped for various reasons, such as long-continued fever, increasing exudate with dyspnoea, anorexia, or deterioration of general condition. The great majority of cases with A.P. at some [illegible]e or another had some degree of exudate which did not [illegible]uire tapping, and are excluded from the figures.

[illegible]f the 169 progressive exudates 59 developed definite [illegible]purulent empyemas in spite of treatment. About one-[illegible]quarter of the exudate cases continued with a satisfactory A.P. while in three-quarters (including the empyemas) the A.P. had to be abandoned because of pleural thickening and diminution of lung function. The view taken, therefore, at the [illegible] of the period was that in every case of progressive tuberculous exudate which did not respond favourably to two or three tappings the A.P. was abandoned and an attempt made to get the lung out to the chest wall by aspiration of fluid and exsufflation of air. If this did not succeed in the course of two to three months the case was regarded as an "incipient empyema" and the surgeon consulted as regards thoracoplasty.

Five such cases in which the effusion was not purulent are included in the present series, with cure following a 5–6-rib thoracoplasty. Probably this deals primarily with the underlying lung focus, preventing reinfection, and the effusion is then completely absorbed after the size of the cavity has been reduced by operation.

Table XI shows the causes of death in the operated series as a whole. The post-operative mortality rate of 18% is high, but it reflects the danger of an extensive operation outside an infected cavity. All the deaths occurred in patients in whom the empyema was over six months old or was secondarily infected, except for the one patient who died of tuberculosis of the opposite lung two years later, the empyema and underlying lung being healed. The implications of this need not repetition.

TABLE XI.—*Unimproved Cases and Causes of Death in Operated Series (55 Cases)*

Group	No.	Unimproved	Died	
			Post-operative Due to Empyema	Due to Lung, etc.
II	2		2 (shock; mitral stenosis)	
III	8 (all except 1 over 6 months)	2 (lung disease)	2 (infection; 1 shock; 1 amyloid—late)	2
IV	5		4 (3 infection (2 perforated pleura); 1 shock)	1
	15	2	10	3

Operative mortality = 18%.

Conclusion

Finally, I would like to stress the aetiological relationship between A.P. treatment and empyema mortality. The recorded incidence of empyema in A.P. treatment is very variable, and depends partly on the differences in treatment and partly on different definitions of an "empyema." Alexander (1937) quotes figures ranging from *nil* (Ulrici, 600 cases) to 21% (Hays, 151 cases). Frostad, in Norway, has estimated it at 10%, as an average figure, and in Söderhjelm's series it was given as "only 7.5%."

A consistent large series from one centre is available at Vardasen (Rogstad, 1948). Great care is taken in the selection of cases and in the technique of closed internal pneumolysis, the director undertaking them all himself. The empyema incidence there is only 6.4% (59 out of 91[illegible] patients). An attempt has been made to distinguish in th[illegible] series between mortality due primarily to the empye[illegible] and that due to the spread of the tuberculous disease. [illegible] far as could be judged, death was due primarily to empyema in 16 cases, or 1.7% of all those in whom A.P. was induced. This not inconsiderable mortal[illegible] therefore due to the A.P. as a method of treatment should be borne in mind when the induction of a p[illegible] thorax is being considered and weighed against th[illegible] methods of collapse of the lung. In certain ca[illegible] e destruction and fibrosis of the lung indicate the n[illegible] Ju of a primary permanent method of collapse, such [illegible] of thoracoplasty. It is certainly incorrect to induce [illegible] the first in practically every case, as is sometimes d[illegible] on the grounds that it is an easy and safe method of [illegible] and therefore should be given a trial.

The misleading factor about the risk of an A.P [illegible]yema being only one, although perhaps the worst, [illegible] com- plications) is that the risk is spread over such a [illegible] period of time that it sometimes fails to impress itself sufficiently on the mind.

Summary

The results in a series of 74 cases of tuberc[illegible]s empyema are discussed and analysed.

A staged thoracoplasty is the standard met[illegible] of treatment used in all cases when the general condition [illegible]mits, supplemented by a Schede and Roberts type of o[illegible]ion in a few, mostly chronic, cases. It should be carr[illegible]out within six months of the onset of the empyema.

In cases without secondary infection and [illegible]rated upon within six months, a limited thoracoplasty (to seven ribs) is often satisfactory.

The treatment of progressive tuberc[illegible]s pleurisy is discussed; if it does not respond to medi[illegible]measures in about three months it is regarded as an "in[illegible]nt empyema," best treated by a limited thoracoplasty.

The risk of the development of a tu[illegible]ulous empyema with resulting mortality following A.P. tre[illegible]nt is discussed.

I would like t[illegible] my sincere thanks to Dr. Carl Semb for his personal [illegible]ring a period of eight months spent in his department, [illegible]gesting the investigation. I would also like to thank the [illegible]bers of the medical staff of Ullevål Hospital and Dr. T[illegible]ers at Vardasen Sanatorium for their unfailing courtesy and [illegible]ess; and, lastly, Sisters Halldis and Krohg without w[illegible]g aid the investigation [illegible] not have been possible.

amides, Pittman type b specific rabbit antise[illegible] and streptomycin. There is, however, at pr[illegible] answer to what is the best line of treatme[illegible]

Previous to the introduction of the sulphonamides, influenzal meningitis was usually fatal. With the use of sulphonamides alone the position was improved a little, but in America a big advance was made by Alexander's (1944) combined treatment with sulphadiazine and Pittman type b specific rabbit antiserum. Using this method she had 68 recoveries in a series of 87 cases. In this country, however, specific antiserum has not been freely available, and the main advance has been made with the use of sulphonamides and with penicillin. Gordon, Woodcock, and Zinnemann (1944) review reports of cases treated with sulphonamides and discuss the response to treatment in relation to the type of organism involved. They record two cases, due to strains not belonging to Pittman type b, who responded to sulphapyridine, and three cases, due to type b, of which only one responded to sulphapyridine. They conclude that prognosis and treatment depend primarily on the strain of the infecting organism. Gordon and Zinnemann (1945) tested the sensitivity of various strains of *H. influenzae* to penicillin and found that 31 of 48 respiratory strains were inhibited by concentrations of 2·5 units per ml. of medium, and 16 out of 18 strains isolated from cerebrospinal fluid were similarly inhibited. They conclude that *H. influenzae* strains are not insensitive to penicillin though the sensitivity is much lower than that of staphylococcal and streptococcal strains. Zinnemann (1946) surveys 20 cases of influenzal meningitis in relation to bacterial types. Of these, 19 were caused by type b. Of five treated with sulphonamides alone two recovered, while of 15 treated with sulphonamides and penicillin eight recovered. McIntosh and Drysdale (1946) report the case of a child aged 2½ years who developed *H. influenzae* meningitis (organism, Pittman type b) during convalescence from meningococcal meningitis and who recovered on treatment with penicillin and sulphamezathine. Drysdale, McIntosh, and Brodie (1946) report recovery in a second case, that of a child of 20 months, treated with penicillin. In this case the organism (Pittman type b) was sensitive to penicillin but insensitive to sulphonamides. Forgacs, Hutchinson, and Rewell (1945) recommend that influenzal meningitis should be treated with a combination of penicillin and a sulphonamide, and report two cases, of which one recovered. Thomson, Bruce, and Green (1947) put on record four cases, of which three recovered; they advocate the use of intramuscular penicillin and an oral sulphonamide along with the intrathecal administration of 50,000 units of penicillin daily until the temperature has been normal for seven days. Gottlieb and Forsyth (1947) report four cases in infants, three of whom recovered on treatment with sulphadiazine by mouth and penicillin given intramuscularly and intrathecally. The strain of *H. influenzae* recovered from the cerebrospinal fluid was found to be insensitive to 10 units of penicillin per ml. of medium but sensitive to 100 units per ml. This justified their use of very large doses of penicillin, and they consider that high systemic dosage is essential in order to prevent relapses due to reinfection of the meninges. They recommend that 20,000–30,000 units should be given intrathecally daily and 120,000 units intramuscularly at three-hourly intervals.

More recently, reports have been made on the value of streptomycin. In the American literature Hoyne and Brown (1948) record 28 cases with only two deaths. All were given sulphadiazine, and in addition some received serum, some had serum and streptomycin, and some (17) had streptomycin. Twenty of the 26 who recovered had no intrathecal therapy, among them being 10 who received oral sulphadiazine and intramuscular streptomycin. These authors consider that not only is intrathecal therapy unnecessary but that it prolongs the time required for recovery.

Case	Age in Years	Sex	No. of Days Ill Before Admission	Cerebrospinal Fluid—First Examination					Penicillin Units (Thousands) Daily × No. of Days		Sulphadiazine Daily Dose × No. of Days	Result

Organism typed in 3 cases only—Type b.

In a report in the *American Journal of Diseases of Children* (1948) of a discussion (in the Transactions of the American Pediatric Society) on the value of streptomycin Alexander states that the use of streptomycin alone in the treatment of influenzal meningitis led to complete recovery when the infection was mild or of average severity; when the infection was severe the result was disappointing, the chief cause of failure being the development of resistance by the organism. In the same discussion Weech reported that he had found Pittman type b to be just as susceptible to penicillin as to streptomycin, while Hodes found that each of 12 strains isolated from patients suffering from influenzal meningitis was more susceptible to penicillin than to streptomycin.

In this country Wilson (1948), in a summary of a report to the Medical Research Council on the use of streptomycin in influenzal meningitis, states that the principal cause of failure was the development of resistance by the organism; this occurred in seven out of nine failures, the sensitivity changing from 0.5 unit to as high as 5,000 units in one to four days. This development of resistance is a serious drawback, and Wilson remarks that "it has been decided in future trials to use a combination of streptomycin, penicillin, and sulphonamides from the start." Smythe (1948) reports 12 cases treated with streptomycin, 10 of which had received previous treatment with penicillin and sulphadiazine. In all of these cases the preliminary dosage of penicillin was not high. He concluded that "streptomycin gave good results in mild and moderately severe cases but was unsatisfactory in three severe cases." Roscoe and Gleeson-White (1948) report four cases treated with streptomycin. In their one fatal case the organism was resistant to streptomycin, and in one of their successful cases the infection was first controlled with intramuscular penicillin, 100,000 units followed by 50,000 units three-hourly for two days and then 25,000 units four-hourly. Relapse occurred on the 15th day, and this was controlled by streptomycin. In the light of the experience of Gottlieb and Forsyth and of our own experience we do not consider that this case indicates a failure of penicillin to cure the disease but that it emphasizes the need for continued high dosage. It is to this point that we particularly wish to draw attention.

Report of 15 Cases

Fifteen cases of influenzal meningitis were treated in the Birmingham Children's Hospital. Two were admitted at the end of 1946, two in March, 1947, and 11 between November, 1947, and July, 1948. Six in the last group were under our care, and for permission to include the other cases in this report we are indebted to our colleagues. Case 1 has already been reported (Gerard, 1947). Twelve of the 15 children are alive, and all are quite well with one exception (Case 3), who is spastic and mentally defective. Details of the cases are summarized in the Table and reports are given below. The incidence of influenzal meningitis among admissions to the hospital is shown in the Chart.

Types of Cases

An evaluation of any line of therapy must take into account the age of the patient, the initial severity of the infection, and the duration of the illness before treatment is begun. It is well established that the mortality is highest in infants. The initial severity can be estimated roughly by the rate of progress to a comatose state, but, apart from that, clinical signs are of uncertain value; chief among laboratory tests is the amount of reducing substance in the cerebrospinal fluid.

Age.—Of the patients whose cases are here recorded two were under 1 year, eight were between 1 and 2 years, four were between 2 and 5 years, and one was over 5 years.

Initial Severity and Duration of Illness

Severe Type.—Cases 6, 7, 8, and 11 were admitted within 24 hours of the onset of illness, and all were comatose or semi-comatose. In the cerebrospinal fluid the cell count was high—2,000–12,000 per c.mm.—and no sugar was present. Three of these patients recovered, and one (Case 11) died within four hours of admission. Cases 1, 4, 9, and 14 were admitted on the second or third day of the illness and were comatose or semicomatose; the cell count in the cerebrospinal fluid was 577–4,000, and sugar was present in two; all recovered. Case 2, aged 1 year, was admitted to hospital on the eighth day of her illness, during the first four days of which "she could not be roused"; she died five weeks after admission. A second (Case 3), aged 7 months, had been ill for two to three weeks and had "seemed far away" for two weeks; she survived, but with permanent cerebral damage. A third (Case 5), aged 2 years, was admitted on the fifth day of illness and died two days later. These three cases draw attention to the difficulty in diagnosing meningitis in very young children and emphasize the disaster consequent on delay in starting adequate treatment.

Less Severe Type.—Case 12, aged 10 months, was admitted on the 10th day of illness; he appeared to have pain in the head, and resisted flexion of the neck, but he was "lively and active." In the cerebrospinal fluid the cell count was 380, sugar was absent, and the protein was 55 mg. per 100 ml. Case 10, aged 1 year 9 months, had been ill for two weeks before admission and was actually under observation in hospital for nearly three weeks before meningeal signs appeared; after some improvement on treatment with relatively small doses of penicillin for pyrexia of unknown origin, a sudden rise in temperature on the 17th day induced us to have a second blood culture, the first, on his admission to hospital, having proved to be sterile. A pure growth of *H. influenzae* was obtained. Lumbar puncture was carried out on the 19th day, neck rigidity having appeared; the fluid contained 1,400 cells, 33 mg. sugar, and 30 mg. protein per 100 ml.; *H. influenzae* was cultured. These two cases demonstrate the long bacteriaemic phase which may precede the meningeal phase: in neither case was the meningitis severe, and both patients recovered

Treatment and Results

The line of treatment adopted has varied somewhat according to the physician responsible for the case and according to experience gained. That and the results obtained will be discussed under three headings.

1. *Sulphadiazine and Penicillin (11 cases)*

(*a*) Three of these patients died. One (Case 11), aged 2½ years, admitted in coma after 24 hours' illness, died before more than one dose of penicillin had been given. Another (Case 2), aged 1 year, had a severe infection and had been ill for eight days: she was comatose on admission. She was given intrathecal penicillin, 40,000 units daily for 12 days, and intramuscular penicillin, 10,000 units three-hourly for 36 days. Irreparable damage may have been done during the eight days before admission, but in any event the intramuscular dose was inadequate. She died on the 36th day of treatment. The third (Case 5) was semicomatose on admission, after having been ill for five days; she was given one dose of 40,000 units of penicillin intrathecally and 50,000 units three-hourly intramuscularly. This dosage we regard as inadequate. She died within 48 hours of admission.

(*b*) One (Case 3) recovered, but had received permanent cerebral damage. She was 7 months old, and had been ill for two to three weeks before admission. Again irreparable damage may have already been done, but doses of only 10,000 units were given intrathecally and 8,000 units, later increased to 30,000 units three-hourly, intramuscularly.

(*c*) Seven cases recovered completely. Six of them were the severe type, comatose or semicomatose on admission; were admitted within 24 hours of the onset of illness and within two to three days; the seventh case had a bacteriaemic phase and the meningitis was not severe (Gerard, 1947), the first in the series, had a prolonged intramuscular dosage over a period of four weeks

intrathecal as well as intraventricular penicillin. Case 4 had 80,000 units of penicillin intrathecally for eight days and intraventricular penicillin, 320,000 units daily, for 17 days. After an immediate good response there was a recurrence of meningitis at the end of the third week, and this was controlled completely by much larger dosage. Cases 6, 7, 8, and 9 were given 5,000 units intrathecally daily and 960,000 units intramuscularly in three-hourly doses. In no case was there any evidence of permanent confusion after the illness was *more under control*, and in no case was intrathecal or intraventricular therapy required. In one case a severe convulsion occurred after the fifth intrathecal injection, but with no ultimate ill effect.

In this last group the cerebrospinal fluid became sterile on the third to fifth day, clinical improvement was apparent in two to three days, and the meningitis seemed to be well under control by the end of a week, though the temperature did not settle completely so long as intramuscular penicillin was given. Also the cell count in the cerebrospinal fluid did not return to normal while the patient was under treatment. This was presumably due to reaction to the penicillin, but in those patients whose C.S.F. has been examined several months after cessation of treatment an ultimate return to normal is indicated. The persistence of pyrexia and cellular reaction, however, made it difficult to decide when to stop treatment: we may have given an unnecessary amount of intrathecal penicillin. There seems to be no need to continue this for more than a week after the fluid is sterile, provided adequate intramuscular penicillin, 960,000 units daily, is continued for about three weeks.

2. *Sulphadiazine, Penicillin, and Streptomycin (3 cases).*—In Cases 12 and 13 a change was made from penicillin to streptomycin on the fourth and fifth day respectively, but in each case improvement in the C.S.F.—a fall in cells from 380 to 80 and a rise in sugar from 0 to 35 mg. per 100 ml. in one, and a fall in cells from 2,540 to 70 and a rise in sugar from 21 mg. to 30.5 mg. per 100 ml. in the other—had already taken place. The second patient had a convulsion after one of the intrathecal injections of penicillin. In the third (Case 14), a change to streptomycin was made on the second day of treatment. In none of these cases can it be said that penicillin had failed: it had not been given time to succeed. All recovered.

3. *Sulphadiazine and Streptomycin.*—One patient (Case 15) was treated with this combination with complete success.

Conclusion

We submit that these cases show that penicillin, combined with oral sulphadiazine, given in adequate dosage—960,000 units daily for three weeks in three-hourly doses intramuscularly, and 40,000 units daily intrathecally for about seven days after the cerebrospinal fluid is sterile—provides an effective remedy in the treatment of severe as well as of moderately severe cases of influenzal meningitis. The facts that streptomycin is not freely available at present and that the organism is known to develop resistance render streptomycin less generally useful.

We wish to express thanks to our colleagues for permission to include their cases in this survey, to the resident medical staff for their help in carrying out the treatment, and to the nursing staff for their great care of the patients. We are also indebted to Dr. Rogers for the pathological reports and to Miss E. Hickmans for the biochemical reports.

A STUDY OF THE POST-WAR INCIDENCE OF BREAST-FEEDING

BY

F. H. M. DUMMER, M.B., Ch.B., D.P.H.

Assistant County Medical Officer, Hertfordshire; Maternity and Child Welfare Medical Officer, Hitchin and Stevenage

This investigation was carried out in order (1) to study the real incidence of breast-feeding in the town of Hitchin, North Hertfordshire (population 20,710); (2) to analyse the reasons for early weaning; and (3) to consider any existing correlation of age and parity, place of confinement, effect of vitamin supplements, mixed feeding, and housing.

Opinions of previous investigators have varied considerably on the trend in breast-feeding. Spence (1938) reported a definite decline; Robinson (1939) stressed the tendency towards a shortening of the duration; Hughes (1942), reviewing the incidence of breast-feeding in a small mining community, found that 31% of babies were weaned by the second week. It has recently been stated that not more than half the babies in Britain are breast-fed for longer than three months (Waller, 1947).

Material and Method

The survey was restricted to mothers living in Hitchin who were confined locally between Jan. 1, 1946, and Dec. 31, 1947, and who spent at least six antenatal months in the district. By such selection it was hoped that variations in antenatal and post-natal care, modes of management in infant-feeding, and fluctuations in the availability of extra rationed goods would be equalized.

In order to obtain a comprehensive survey it was obvious that the records of antenatal and infant welfare clinics alone would be inadequate. A detailed questionary was therefore prepared and mothers in the above category were interviewed individually. The questions were worded so that a "social history" of each infant could be built up. A complete picture of environmental conditions possibly affecting its intrauterine and extrauterine life until the age of 6–9 months was obtained. Out of all the visits paid, in only one instance was the required information refused.

The results of the questionary, taken in conjunction with the relevant records in the clinics and the reports of the health visitors, provide the basis of this study.

Results

Omitting infant deaths, removals from the district, and mothers who were confined elsewhere, the total available for investigation was 546. The number successfully interviewed was 545. Of these, 58.7% were in regular attendance at the infant welfare centre. This figure is regarded as satisfactory, since over 30% of mothers with children born in 1946–7 are living in an area of the town almost two miles from the centre, and their regular attendance would be a matter of great inconvenience to them.

Deliveries.—These were carried out in the County Council Maternity Home (161), two private nursing-homes (230), the

maternity unit of a local hospital (50), and "on district" (104). Midwives delivered 383 cases, while 162 were doctors' cases. The overall average period "confined to bed" was 11.1 days.

Age and Parity.—Almost one-quarter of the primiparae were aged 30 or over (Table I). Although the number of primiparae is high—44%—the tendency towards postponement of the first birth is seen. The average time which elapsed between marriage and the birth of the first child to *the primiparous group* was 3.4 years. Less than 27% have more than two children.

TABLE I.—*Age and Parity*

Age	Para									Total
	1	2	3	4	5	6	7	8	8+	
18—	26	2	1							29
22—	87	25	6	1		1				120
26—	72	38	12	7	2	1				132
30—	35	48	18	11	6	3	1			125
34—	14	31	15	8	5	3	4	1		81
38—	5	11	14	8	6	4	2	2	1	53
42+		2			1		1		1	5
Total	242	157	66	35	20	12	8	3	2	545

Duration of Breast-feeding.—In Table II "weaned" is defined as "having reached the stage at which the infant receives wholly, for the first time, feeds other than breast milk." These results are compared with those of previous investigations

TABLE II.—*Duration of Breast-feeding (545 Cases)*

Time	Complete Breast-feeding	Partial Breast-feeding	Weaned
At birth	84·8%	5·5%	9·7%
Up to 2 weeks	78·3%	2·4%	19·3%
1 month	69·5%	4·5%	26·0%
2 months	57·5%	6·5%	36·0%
3 ,,	50·3%	2·7%	47·0%
4 ,,	40·7%	5·3%	54·0%
5 ,,	30·25%	9·0%	60·75%
6 ,,	13·2%	18·4%	68·4%

TABLE III.—*Duration of Breast-feeding. Comparison with Previous Investigations*

Time	Spence (from Findlay, Edinburgh), 1938 (3,000 Cases)	Spence (from Brewis, Newcastle) 1938 (1,326 Cases)	Robinson, Liverpool, 1937 (439 Cases)	Hughes, Newbiggin, 1942 (112 Cases)	Present Survey 1948 (545 Cases)
10–14 days	87%	—	—	—	—
2 weeks	—	—	86%	67%	78·3%
1 month	—	—	—	55%	69·5%
3 months	—	55%	48%	32%	50·3%
3–6 ,,	55%	—	—	—	—
6 ,,	—	34·7%	29%	19%	13·2%

(Table III). Since the factor of "duration" is of greater consequence than "initial incidence" the results were further broken down to ascertain the trend of primiparous women (Table IV).

TABLE IV.—*Duration of Breast-feeding: Primiparae (242 Cases)*

Time	Complete Breast-feeding	Partial Breast-feeding	Weaned
Up to 2 weeks	75%	9%	16%
1 month	66%	11·5%	22·5%
3 months	50%	4·2%	45·8%
6 ,,	12·8%	18·2%	69%

Complementary Feeding.—Table V shows the average period for which mothers have been able to extend breast-feeding by the use of complementary feeds. Cases in which full breast-feeding was later resumed have been excluded.

TABLE V.—*Showing the Duration of Breast-feeding along with Complementary Feeds*

Complemented at	Average Extension of Breast-feeding	Complemented at	Average Extension of Breast-feeding

2 weeks	5·3 ,,	12 ,,	10·0 ,,
3 ,,	7·3 ,,	16 ,,	9·1 ,,
4 ,,	6·0 ,,	18 ,,	9·8 ,,
5 ,,	7·3 ,,	20 ,,	11·9 ,,
6 ,,	6·6 ,,	22 ,,	10 ,,

Place of Confinement Related to Weaning.—The results are shown in Table VI.

TABLE VI.—*Percentages Weaned at 14 Days and 3 Months Referred to Place of Confinement*

Place of Delivery	Weaned by 14 Days	Weaned by 3 Months
County Council Maternity Home	16·2%	53·4%
Private nursing-homes	18·2%	45·4%
District	23·1%	50%

Housing.—Details of housing accommodation for the first six post-natal months were carefully noted, and cases were allocated to one of the six categories shown in Table VIII. The special position of primiparae was ascertained.

TABLE VII.—*Showing (i) Housing Distribution; (ii) Percentage Weaned by 8 Weeks; (iii) Percentage of Primiparae Weaned by 8 Weeks*

Group	Sharing	Detached	Semi-det	Flat	Rooms	Indoors
(i) Overall	8·1%	7·2%	48·8%	9·1%	11·7%	15·4%
(ii) Weaned by 8 weeks	25·0%	25·6%	33·4%	31·2%	32·6%	40·0%
(iii) Weaned by 8 weeks (primiparae)	63%	20·0%	29·0%	27·0%	50%	65%

Vitamin Supplements.—It might be of some interest to note the percentages using the Ministry of Food vitamin supplements A and D and the concentrate of orange juice available for expectant mothers: (1) 27.3% did not use the supplements at any time; (2) 11.8% took the supplements in both antenatal and post-natal periods; and (3) 60.9% took them in the antenatal period only. For either period the minimum time allowed in the calculations was one month and the maximum six months. In group 1, 25.1% breast-fed for three months or more; in group 2 the figure was 12.3%; and in group 3 42.6%. No real relationship is suggested in these findings.

Reasons for Weaning.—The reasons for weaning by the end of the third month were: maternal illness general, 9%; maternal illness, local, 15%; illness of infant 5%, economic, 4%; psychological, 10%; physiological 5%; miscellaneous, 6%. Among the above causes breast troubles accounted for 4%, *mastitis or engorgement with or without abscess formation* or malformation of nipples or breasts 5%, and infant malformations such as cleft-palate and hare-lip 1%.

Occupational Groups.—Apart from illegitimate confinements, in all but two cases the occupation of the husband was accurately elicited. Table VIII covers the occupational groups of 97% of the husbands of the women interviewed.

TABLE VIII.—*Showing Occupational Distribution of Weaning Times*

Occupation	Percentage Weaning Occurring at			
	0–4 Wks	5–12 Wks	13–24 Wks	After 24 Wks
Professional	13	15	22	30
Civil servants	14	22	26	28
Skilled workers	12	21	16	39
Services	15	25	15	25
Semi-skilled workers	31	27	19	23
Storekeepers	25	17	30	28
Vehicle drivers	22	22	32	24
Factory workers	31	15	15	39
Labourers	30	22	23	25

Discussion

From a study of previous investigations it is clear that there is a distinct trend towards early weaning (Spence, 1938; Robinson, 1939; Hughes, 1942). The likelihood this mode will become permanent is given weight by fact that the gross initial incidence of breast-feed not fallen to any appreciable extent. Of the 242 p in this series 16% had weaned by the end of the and of these nearly one-half had either not feed the infant or had failed to establish succ

in the first week. In the analysis of the reasons for weaning at or before 3 months 6% were classified as being unwilling to breast-feed.

Genuine physical incapacity of mother or infant amounted to only 6.1%. Spence (1938) considers that not less than 5% of failures in lactation are due to this cause.

The term "physiological insufficiency" covers a multitude of unsatisfactory causes. In this group the commonest explanation was "My milk just dried up." Where there was any reason to suspect undue worry, shock, or housing conditions which were too bad for a nursing mother to cope with there has been a follow-up, and the reason re-allocated. But a large percentage of failures remain unexplained. In a study of failing lactation Robinson (1943) found that in 40% of women who ceased breast-feeding before the end of the seventh month no adequate reason could either be given or be found on examination. There would seem to be no specific fault, and in the majority of cases the mother insisted that she wished to persist in breast-feeding. In many instances it is not unlikely that the reason was an unadmitted revolt against the conditions in which she was placed—tiredness, small accumulating worries, living under poor or even bad conditions, restriction of freedom, and, possibly, marital anxieties. In such cases home help, the health visitor's continuing interest, and, perhaps most important of all, the attitude of the husband would give the nursing mother that peace of mind and bodily rest so essential throughout lactation. It is not unknown for the husband to forbid breast-feeding. One such individual gave as his reason, "Breast-feeding is a disgusting example to our 12-year-old daughter."

The "danger period" in breast-feeding is primarily at the fourth or fifth week, with a second relapse about the tenth or twelfth week. The value, or otherwise, of complementary feeds at such times has been strongly voiced (Lishman, 1944; Hughes, 1942). We have found that even in the early stages many mothers are enabled to resume full breast-feeding after the use of small complementary feeds for only a week or ten days. It is true that a large number of mothers give up, and no aspect of infant feeding is fraught with greater disappointment.

The use of a single 2-p.m. test feed can be very misleading. It is here that the clinic medical officer—and, no less, the practitioner—faces a substantial obstacle. It helps considerably to have mothers for test feeds encouraged to attend the clinic slightly earlier than the normal session so that one may examine the breasts before the feed and again during the feeding. In really co-operative cases—and the fullest co-operation is an essential in early complementary feeding—the health visitor can usually arrange to carry out three consecutive test feeds, or at least a minimum of two, including the one at the clinic. Complementary feeds at the later stages—from the eighth week onwards—can be resorted to more confidently.

In a pre-war study Robinson (1939) found that of the 67 primiparae living in rooms in 100 consecutive cases approximately 70% had weaned by eight weeks. In the present survey the highest percentage of weanings occurs in those occupying rooms or in the even more indefinite menage with "in-laws." Naturally, the greatest number of primiparae are also found in those circumstances. The effect of "friends and relations" can be thoroughly disheartening to the inexperienced, and I am of the opinion that housing difficulties as they exist at present, and the close proximity of relations, together constitute a major menace to successful breast-feeding. This position may have some bearing on the unsatisfactory district figures compared with those of nursing-homes on the question of weaning by the end of the second week.

In the Ministry of Health Report (1944) the statement is made that the Advisory Committee estimated that 95% of babies born on the district are wholly breast-fed when the midwife leaves, while only 80% of babies leave hospital fully breast-fed. For these results the "over-mechanized methods" of hospitals are blamed. In this series 83.8% of babies born in the County Council Maternity Home were wholly breast-fed at 14 days, while the corresponding district figure was 76.9%. Locally, at least, "over-mechanized methods" do not appear as an outstanding cause of failure.

This investigation shows that each of the occupational groups chosen has its own specific weaning rate. In her Liverpool series on the weaning rates in ten classes of the population in the years 1930–40, Robinson (1941) found a difference of only 8% at the end of the first month and only 3% between the classes at the fourth to seventh months. The smallest range—12%—in the present survey occurs between the fifth and twelfth weeks. In a series of this size we are not justified in drawing general conclusions from these findings.

From the collected material available it is unfortunately not possible to give accurate morbidity rates relative to breast-feeding; it was established, however, that no case of gastro-enteritis requiring treatment in hospital had occurred in babies who had been wholly breast-fed for three months or longer.

Summary

The results of an investigation into the incidence of breast-feeding in an area of North Hertfordshire in 1946–7 are analysed.

The number of babies completely breast-fed at 6 months was estimated at the low figure of 13.2%.

Although the primary incidence of breast-feeding has not appreciably altered there is evidence of a shortening of the duration. The "mode" in breast-feeding is set by the primiparae, who favour the shortened duration.

An evaluation is made of complementary feeding.

The effects of housing accommodation are tabulated and discussed.

A comparison is drawn between the early weaning rates of babies born in maternity homes and those on the district.

I have to thank Dr. J. L. Dunlop, county medical officer of Hertfordshire, for permission to undertake this investigation, and the staff of the County Health Department for their interest and assistance. Most of the interviews were carried out by the health visitors of Hitchin, and I am most deeply indebted to them for their sustained interest and the willingness with which they agreed to perform these additional tasks. The permission of the Librarian of Cambridge University Library to peruse the medical literature is also gratefully acknowledged.

ASCHHEIM-ZONDEK AND HOGBEN PREGNANCY TESTS MODIFIED AND COMPARED

BY

F. W. LANDGREBE, D.Sc.

AND

B. M. HOBSON, B.Sc.

(From the Department of Public Health and Social Medicine, University of Edinburgh)

During 1948 the new laboratory of the Pregnancy Diagnosis Station of the University of Edinburgh was equipped to carry out the Hogben test. Most of the tests now carried out here are Hogben tests, though a large proportion of Aschheim-Zondek tests are still performed, partly because many practitioners do not send us enough urine.

Modifications

During this period modifications to both methods have been introduced which have resulted in a more efficient routine and in greater accuracy. There are now enough data available to show that the Hogben test is suitable for routine diagnosis, and that it is more reliable than the Aschheim-Zondek test. The following modifications are those now in use.

1. Aschheim-Zondek Test

The method used is that described by Robson (1947), with the following modifications. Four mice (obtained from dealers as 3-weeks-old females) are used instead of five. The pretreatment of urine (testing with universal indicator, addition of acid, or shaking with ether when toxic) and the addition of 1 g. of sulphosalicylic acid to 30 ml. of urine have been discarded in favour of the following: four drops of 20% thymol in alcohol are added to 30 ml. of urine immediately on arrival of the specimen. This simple modification has reduced the percentage of urines which prove toxic to the test mice. This is in conformity with the findings of Zondek and Black (1946), who decided that toxicity was not a property of normal urine, but was formed, on standing, by bacteria in the urine. It should be added that the mice tolerate thymol extremely well, and the effect on the ovaries of the test animals seems more clear-cut.

2. Hogben Test

The method used is that published by Landgrebe and Samson (1944), with the following modifications. Well-fed toads weighing 60–100 g. are used, and must respond by ovulating to 70 i.u. of chorionic gonadotropin instead of 100 i.u. We find that stock animals can be divided into two quite distinct groups with regard to sensitivity, and this test dose enables the less sensitive animals (about 20% of a fresh stock) to be discarded. Toads are used every ten days, as they have been shown to be more sensitive than if used at 21-day intervals (Landgrebe, 1948). They are not, however, used continuously, because they lose weight. It may be that with different conditions of husbandry this would not occur. So in our laboratory they are used three times in one month and the next month not at all—e.g., animals used on Jan. 3, 13, and 25 will be rested during February and used again on March 1, 11, and 23, resting the following month, and so on. This means that a single *Xenopus* toad is used 18 times in a year.

By means of the Scott (1940) technique 60 ml. of urine are concentrated into 5 ml. of extract. One toad only is used for each test, and it receives 2.5 ml. of extract in the dorsal lymph sac (see Landgrebe, 1948). If the toad ovulates within 24 hours the result is recorded as positive. If, however, no ovulation results in 24 hours a second toad is injected with the remainder (2.5 ml.) of the same extract. If both toads are still negative 48 hours after the beginning of the test the result is recorded as negative. This enables 25% more tests to be done with the same number of test animals without loss in accuracy. We find that toads which have previously ovulated can be made to deposit eggs if they are injected, 24 hours after their last ovulation, with "negative urine" or distilled water. It is therefore of the utmost importance that toads be taken from the correct tanks, otherwise many false positive results will be obtained.

Comparison of Results

Slips for confirmation or otherwise are sent out with the results of the tests, but unfortunately owing to lack of co-operation of the medical practitioners only 14% were returned during 1948. It has been assumed in the following table that our errors are duly reported. In the words of one of our local practitioners, "I don't bother to tell you when you are right, but I soon let you know if you are not." Even if this assumption is incorrect the comparison between the two methods is still valid, as a similar proportion of confirmations were received for each test. The first items in the accompanying Table are a summation of data gleaned from the literature.

Test	Source	No. of Tests	Definitely Correct	Doubtful	False Negative	False Positive
A.-Z.	42 authors	26,163	97·9%			
	13 "	5,455	97·2%	0·05%	1·6%	1·2%
	Edinburgh P.D.L.	12,567	99%	0·18%	0·72%	0·09%
Hogben	14 authors	7,707	98·9%	0	1·1%	0
	Edinburgh P.D.L.	5,666	99·65%	0	0·32%	0·03%

It will be seen that the Hogben test has produced more reliable results than the A.-Z. test both at Edinburgh and elsewhere—this in spite of the fact that our modification of the A.-Z. has increased the accuracy from an average of 98.4% over many years to 99% in 1948.

The number of false positives (two) given by the Hogben test compares favourably with that given by the A.-Z. test. One of these Hogben false positives was found with urine from a patient with a history of persistent abortion over several years. According to the clinical report received later, she had a discharge for a few days following the dispatch of the specimen. The second false positive did not, however, support the clinical findings, although two toads ovulated to the specimen of urine sent. Thus any attempt to sensitize the test further should be avoided.

Some false negative results are probably due to specimens being collected too soon after the first missed period: ten days should elapse before urine is sent for test. We cannot decide how many of our false negative results are due to this, since in many cases little or no information is sent with specimens of urine.

Conclusion

It is shown that the Hogben is a more reliable test than the A.-Z. Its many other advantages over the A.-Z. have been outlined by several different authors (Elkan, 1946; Herring, 1944; Landgrebe and Samson, 1944; Milton, 1946; Weisman and Coates, 1944; Zwarenstein and Duncan, 1944). With our modifications the advantage of economy is even more obvious. Some of our animals have been used for test over 40 times and are giving consistent and reliable results. We have estimated that, including running costs of the laboratory, a Hogben test can be carried out at less than half the cost of an A.-Z. test

A SIMPLE WEIGHT-REDUCING DIET

BY

H. L. MARRIOTT, C.B.E., M.D., F.R.C.P.
Physician With Charge of Out-patients, Middlesex Hospital

Fifteen years ago I devised a reducing diet, and have since used it for a large number of patients. The essential instructions are as follows:

1. Eat or drink as much as you like (or can get) of :

Lean meat, poultry, game, rabbit, hare, liver, kidney, heart, sweetbread—cooked in any way, but without addition of flour, breadcrumbs, or thick sauces.

Fish (not tinned), boiled or steamed only ; no thick sauce.

Eggs, boiled or poached only.

Potatoes, boiled, steamed, or baked in skins, but not fried, roast, sauté, or "chips"; not potato powder.

Other vegetables of all kinds (fresh, tinned, or dried) *cooked in any way not involving the use of fat.*

Salad and tomatoes without oil or mayonnaise.

Beetroot, radishes, watercress, parsley.

Fresh fruit of any kind, including bananas. Also bottled fruit if bottled without sugar. Not tinned or dried fruits (including dates, figs, and raisins).

Sour pickles, not sweet pickles or chutneys.

Clear soup, broth, "bovril," "oxo," "marmite."

Salt, pepper, mustard, vinegar, Worcester sauce (no other sauces).

Saccharin for sweetening.

Water, soda-water, and non-sweetened mineral waters.

Tea and coffee (milk only as allowed below).

2. You may have milk (not condensed) up to half a pint (284 ml.) daily. No cream.

3. You may have three very small pieces of bread per day and take them either one at each main meal or all three at one meal as desired ("very small" means not exceeding 1 oz.—*28 g.*).

4. You may have *nothing else whatever*; particularly note that this means :

No butter, margarine, fat, or oil (except for cooking meat, *not* fish).

No sugar, jam, marmalade, honey, sweets, chocolate, cocoa.

No puddings, ices, dried or tinned fruits, nuts.

No bread (except as above), cake, biscuits, toast, patent reducing breads, cereals, oatmeal, "all-bran," "ryvita," "vitawheat."

No barley, rice, macaroni, spaghetti, semolina, sausages, cheese.

No cocktail savouries, alcohol (beer, cider, wines, and spirits).

Weigh before you begin, and thereafter weekly, on the *same scales*, in the *same clothes*, and at the *same time* of day.

The general principle of the diet is simply to allow unrestricted consumption of specified low- and moderate-calorie foods, with measurement of only two foods, milk and bread. It is therefore very simple, and patients generally report it as easy to carry out, even in these days, whether eating at home or in restaurants or as guests.

The opening words "eat or drink as much as you like" seem to predispose to willing co-operation. Encouragement to eat unlimited potatoes generally occasions pleasant surprise. The lay public has deeply rooted the notion that potatoes are more fattening than anything else and, consequently, the obese have usually been denying themselves potatoes, which, in fact, are not of high calorie value unless covered and impregnated with fat in cooking. Obese subjects can eat liberal helpings of boiled, steamed, or baked (without fat) potatoes three times a day and still continue to lose weight.

Weight lost by patients who adhere faithfully to the diet, without any lapses, varies from 15 to 35 lb. (6.8 to 15.9 kg.) in 12 weeks. More can be lost (up to 60 lb. (27.2 kg.) in the very fat) by going on. Prolonged experience enables one to say that a patient with simple obesity who does not lose weight is eating or drinking outside the permitted articles.

After weight reduction has been achieved the patient is left knowing the foods which are most fattening. He or she should be advised to return to ordinary diet but to maintain weekly weighing and check any observed tendency to regain weight by moderate restriction of consumption of the articles listed in Instruction 4.

Hitherto I have not had the diet printed, except for hospital use, but in response to requests from practitioners I have arranged with Messrs. H. K. Lewis & Co., Ltd., 136, Gower Street, W.C.1, to produce it as a printed diet card with the instructions on the front and the weight record on the back. (Price 7d. post free.) The instructions are prefaced by a warning that the diet should not be undertaken except on the advice and under the supervision of a doctor. A footnote states that the card is intended for sale only to registered medical practitioners.

Medical Memoranda

Pylorospasm in the Adult, Complicated by Uraemia

In the *B.M.J.* of Jan. 17, 1948 (p. 99), Mr. A. Hobson mentions the connexion of hypertrophic pyloric stenosis with uraemia. I have recently treated a case similar to his, although mine was undoubtedly pylorospasm instead of true hypertrophic stenosis.

In Price's *Practice of Medicine (1938) it is remarked* that "spasm is often stated to give rise to pyloric obstruction, but the evidence that it can do so is inconclusive, except in the hypertrophic pyloric stenosis of infants." In contrast to this, Beckman (U.S.A.) in his *Treatment in General Practice* under the headings of "nervous dyspepsia" and "pylorospasm" describes cases very similar to that of my patient.

CASE REPORT

In January, 1916, while in the Army, a professional man now aged 60 had jaundice with acute pain and was in hospital for four months. In September, 1916, he underwent appendicectomy for alleged chronic appendicitis, and has suffered from flatulent dyspepsia ever since. He was first seen by me in December, 1919, when he had a temperature of 102° F. (38.9° C.) and a much-enlarged and tender gall-bladder.

In January, 1927, he still had flatulent dyspepsia, and cholecystography on two occasions failed to show the gall-bladder. The report on a barium meal was that the first, second, and half the third part of the duodenum were enormously dilated, possibly by obstruction by the superior mesenteric artery. On my advice an exploratory laparotomy was done. The gall-bladder was removed, but was found to contain no calculus and did not seem to be unhealthy. From this time flatulent dyspepsia had persisted more or less continuously with bouts of vomiting. Barium meals on several occasions showed no abnormality of stomach or duodenum. In March, 1946, he had jaundice with relapse, presumably due to infective hepatitis, which was epidemic at the time. During the summer of 1947, while on holiday in England, he was very ill, vomiting frequently and losing a great deal of weight. He was admitted to hospital, and after barium and fractional test meals was told he was suffering from "cramp of the stomach," which in the light of recent events presumably meant pylorospasm.

I saw him in October, 1947. He was then extremely thin, but stool culture revealed nothing abnormal. By the middle of January, 1948, he had been free of symptoms for three months, had been eating less carefully than for a long time, and had gained some 18 lb. (8.2 kg.). This ruled out any possibility of carcinoma. It was quite evident that his symptoms were closely related to worry, of which he had been free during these three months. On Jan. 20 he relapsed. He now restricted his food, but had vomited several times daily for a week. His subsequent history is as follows:

Jan. 22.—Still vomiting; mental confusion and delusions. Admitted to hospital. Urine: a few granular and hyaline casts; traces of albumin; sp. gr. 1014. Blood urea 172 mg., plasma chlorides 415 mg. per 100 ml.

Jan. 23.—No more vomiting. Urine 14 oz. (400 ml.). Rational at times. B.P. normal. Glucose-saline, 500 ml. b.d. subcutaneously; orange juice, etc.

Jan. 24.—No vomiting. Great mental confusion.

Jan. 25.—No vomiting. Urine, 70 oz. (2 litres). Blood urea, 200 mg. per 100 ml. No noteworthy change occurred for five days.

Jan. 30.—Urine, 70 oz. Blood urea, 72 mg. per 100 ml.

Feb. 1.—Urine, 30 oz. (850 ml.). Vomited copious green fluid several times.

Feb. 2.—Urine, 34 oz. (965 ml.). Copious vomiting.

Feb. 3.—Copious vomiting of green liquid. On inspection very strong peristaltic waves visible in epigastrium, with a swelling as large as a tangerine orange progressing towards the pylorus, as seen in congenital pyloric stenosis of infants. Barium meal: on screening, very strong peristalsis of stomach with antiperistaltic wave after it had reached the pylorus. Two-and-three-quarter hours later no barium had passed the pylorus. Atropine 1/100 gr. (0.65 mg.) subcutaneously; "bellafoline" 10 minims (0.6 ml.) t.d.s.; phenobarbitone ¼ gr. (50 mg.) t.d.s.; glucose-saline 500 ml. b.d.

Feb. 4.—No vomiting. Urine, 20 oz. (570 ml.).

Feb. 5.—No vomiting. Atropine, 1/200 gr. (0.32 mg.) b.d.

Feb. 6.—Copious vomiting. Atropine and bellafoline discontinued. "Antal" 10 ml. I.V. daily for 18 days. (Antal is a French preparation containing 1 mg. of atropine and some sodium bromide.) It was noticed that the very violent peristalsis of the stomach which occurred after the ingestion of any food ceased in a few minutes after the injection of antal; the patient then announced that the spasm had relaxed, and food was passing the pylorus.

On Feb. 20 he was eating cold chicken and ham without inconvenience and had returned to work in his office.

Nov. 10.—For four months past he has been free of all symptoms, eating normally, and feels better than he has done for 25 years.

I believe the "cure" to be due to his realization that the gastric trouble was due to psychological causes.

Anglo-Swiss Hospital, Alexandria, Egypt.

Sternal Swelling as a Presenting Sign of Hodgkin's Disease

The association between sternal swellings and Hodgkin's disease has been noted by Goldman and Victor (1945) and by Sicher (1948). The latter describes an unusual case in which Hodgkin's disease manifested itself by a sternal swelling of two weeks' duration. The following case is of interest in that a swelling had been present on the sternum for five years before the diagnosis of lymphadenoma was made, and because the patient had been successfully treated for pulmonary tuberculosis.

CASE HISTORY

The patient, a woman aged 36, with a considerable medical history, was notified to this department in July, 1947, as a case of tuberculosis, and was admitted on Aug. 11 to sanatorium for further investigation.

She had had measles and scarlet fever, injuries due to a fall of 30 ft. (9.14 m.) at the age of 13, and pulmonary tuberculosis at 22. She was in sanatorium from July, 1933, to January, 1934, and was treated by left A.P., which was continued privately thereafter; last refill January, 1946. Menstrual disorders for years; had D. and C. in 1943 and again in January, 1947. Chronic dermatitis of both hands.

A small swelling on the upper sternum first noticed about 1942 had remained static. After the uterine operation in January, 1947, the swelling had enlarged noticeably and progressively. In June, 1947, the condition was diagnosed as tuberculosis, and the case was notified to the public health department.

When I first saw her in July, 1947, her general condition was fair. She was febrile, toxic, and anaemic, but, apart from the swelling and some weakness, had no complaint. The lungs showed signs of fibrosis but none of any active disease. The cardiovascular, digestive, and nervous systems were clinically normal. The dermatitis of both hands was in a quiescent phase, but there was slight dry eczema of the webs of the fingers.

The swelling was a rounded painless protuberance on the upper sternum about the level of the second costal cartilages. It was exactly in the midline and occupied almost the breadth of the sternum. There was no tenderness or sign of pointing, but the overlying skin was reddened and fluctuation was present. No parasternal lymph nodes were detected. Aspiration was completely unsuccessful. Radiography of lungs and thorax revealed very slight old fibrosis in the right mid-zone, denser fibrosis in the left mid-zone with pleural thickening, but no sign of active disease or of hilar enlargement. The radiologist also reported a large round swelling of the soft tissues of the sternum both anteriorly and posteriorly about the second rib level; no erosion of the sternum was observed, but the anterior end of the second left rib was ill-defined. Other clinical findings were enlarged glands in both axillae but no adenopathy elsewhere; red cells, 3,730,000; Hb, 53%; white cells, 15,400; B.S.R., 51 mm./hour.

When she was admitted for sanatorium observation on Aug. 11 no definite diagnosis had been made. While various possibilities were recognized, tuberculosis was considered the most probable cause, especially in view of her previous history. On Sept. 4, however, biopsy of glands from the right axilla revealed changes typical of lymphadenoma. The patient was thereafter transferred to a general hospital where she received deep *x*-ray therapy, and was discharged on Nov. 21. Since then she has gone to live in the country and has not been examined, but is known to be fairly well (November, 1948).

I have to thank Dr. S. I. A. Laidlaw, Medical Officer of Health, Glasgow, for permission to publish this case.

Reviews

THE NOSE AND THROAT

Diseases of the Nose and Throat. By Sir StClair Thomson, M.D., F.R.C.P., F.R.C.S., and V. E. Negus, M.S., F.R.C.S. Fifth edition. (Pp. 1,004; with 13 colour, 20 radiographic, and 11 other plates, and 369 figures. £3 10s.) *London: Cassell and Co.* 1948.

This admirable textbook, originally the work of Sir StClair Thomson, has held its leading position since the first edition in 1912. Mr. Negus has kept alive the spirit of the work while adding all advances in knowledge of the subject since the previous edition of 1937.

In the preface Mr. Negus writes: "I commend this book as a monument to its founder and sincerely hope that his spirit will illuminate the work by which the world may recognize and remember him, even though he did not survive to celebrate its completion." Readers will agree that this is certainly so. A book of this calibre gives the reviewer little scope for criticism, only the pleasure of praise; it is most comprehensive. The student will find all he needs and more, and the laryngologist will gain much from the well-balanced views on diagnosis and treatment, which are given in great detail. The writing is scholarly, and at the most there are only two misprints: a few sentences, evidently taken from previous editions, give a feeling of unreality to-day.

The era of antibiotics and chemotherapy has so changed the clinical picture of many diseases which, regarded as dangerous or even fatal in the past, are now susceptible of cure in a matter of days or even hours, and this aspect of medicine is perhaps not sufficiently emphasized.

The subject-matter is divided into thirteen parts: the first concerns embryology and physiology, methods of examination, treatment, and prevention of operative dangers. Under the heading of treatment wise advice is given on what not to use in nasal sprays, and on the use and abuse of cocaine. There is also a clear description of the methods of administration of the sulphonamides and penicillin, though doses at present are larger than those suggested. It is scarcely necessary to-day to give advice about anaesthesia, since this is now in the hands of experts. Conditions affecting the nose are described in part two. Stress is laid on the importance of proper respect for the ciliary mechanism and all this respect implies. The descriptions of nasal accidents and diseases are good and well illustrated, though exception may be taken by the plastic surgeon to the mention of the hinged cartilage graft for the correction of nasal deformity. There is an excellent chapter on allergy.

The paranasal sinuses are discussed justly, and the various operations and their dangers fully explained. For rhino-dacryocystostomy West's operation is preferred to that of Dupuy-Dutemps, a view which is not held by all. Crook's method of washing out the antra in children, under cocaine analgesia, is adequately described and illustrated.

Part four—on growths of the nose and sinuses—is admirable. For growths of the antrum and ethmoid a combination of deep *x* rays and surgery (using diathermy) is advocated, with removal of the hard palate to allow of thorough inspection of the cavity. This treatment is supported by statistics. It is suggested that growth may originate in or involve the frontal sinus, but the great rarity of this might well have been mentioned.

Parts five and six, which are concerned with the naso-pharynx, pharynx, and tonsils, occupy 190 pages and clearly express the present-day views on the "tonsil and adenoids" question. The La Force instrument for removal of adenoids is preferred, as doing least damage to the mucous membrane. Good pictures illustrate the different operations. Differential diagnoses of tonsil infections are given fully. Pharyngeal pouch is stated to arise in the middle line, though anatomically it would seem that the origin should be at one side of the posterior median raphe.

Diseases of the larynx are described in part seven. If one part of this work should be praised more than others it is this. It embodies all Mr. Negus's knowledge, gained from his researches into the comparative anatomy of the larynx and his wide clinical experience and exact observation. These words are particularly applicable to the chapter on the laryngeal paralyses, which make a complicated subject appear very easy. The excellent diagrams will prove a great help to the reader. For the treatment of double abductor paralysis a permanent tracheotomy with a tube incorporating a one-way flap valve is preferred to any other operation. In the description of the treatment of nodules on the cords not enough emphasis is laid on the excellent results of treatment by skilled teachers of voice production, which cures nodes far more quickly than weeks of silence, as advised.

For the treatment of epithelioma of the vocal cord laryngo-fissure is given preference over radium or radon needles inserted through a window in the thyroid cartilage. The descriptions of laryngo-fissure and of laryngectomy are clear and fully illustrated, some of the pictures being those by the late L. Colledge.

An account of diseases of the trachea and bronchi naturally follows in part eight, and exhibits the wide experience of the author. Special points are illustrated by *x* rays, some after lipiodol injection. The author proves, if proof be needed, that bronchoscopy in the hands of the laryngologist has its place.

Part nine deals with the oesophagus. It begins by describing congenital deformities, strictures, and growths and their treatment. An account is given of the author's ingenious method of inserting radon seeds, coupled by links of catgut, round malignant growths through an oesophagoscope. There follows a well-illustrated chapter on the neurological disorders, including achalasia. Dilatation with Hurst's mercury tube or a dilating bag is recommended, and operation is stated seldom to be necessary. Foreign bodies in the air and food passages are fully discussed and their complications explained with *x*-ray reproductions. A separate chapter is devoted to the technique of endoscopy.

The volume concludes with detailed descriptions of chronic infections, tuberculosis, syphilis, and rarer conditions—e.g., glanders, actinomycosis, and scleroma. There is also an account of the acute specific fevers. Lastly, a list of prescriptions is given, with the amounts of the ingredients expressed in English and metric measures.

This book must be in every laryngologist's library. It is so comprehensive that few will not learn something from it, and if the reader desires more detailed information on any particular subject there are full lists of references at the end of every chapter. It is profusely illustrated and contains thirteen excellent colour plates.

W. M. MOLLISON.

LABORATORY ANIMALS

The U.F.A.W. Handbook on the Care and Management of Laboratory Animals. With an Appendix on Statistical Analysis. Edited by Alastair N. Worden, M.A., B.Sc., M.R.C.V.S., A.R.I.C. With foreword by [illegible] ing, M.A., M.R.C.V.S., F.R.S.Ed. (Pp. [illegible] 31s. 6d.) *London: Baillière, Tindall and Cox.* 1947.

What etymological quirk has decreed that a humanitarian is a person with kindly feelings for men and other animals, whereas a philanthropist confines his abounding affection to his own species? No answer to this question being known to me, I suggested many years ago that some new word such as philozoist, zoophilist, or even animalitarian was needed to attach to those concerning themselves specifically with the welfare of the animals that we group together as *dumb*—though many of them are far from that. However, this proposal having been rejected with enthusiasm, I must run the risk of misunderstanding if I declare that this book is a very practical blend of economics and humanitarianism.

Professor Worden and his colleagues are preaching to a simple text—namely, that in the long run it pays to be kind to animals, and to none more than to the dozen or so species used in scientific laboratories in those types of research and control work for which living animals are indispensable. Common sense, not sentimentality, provides the authors with their keynote. "You can," they say, in effect, "get with healthy contented animals more information from the same number, or the same amount of information from a smaller number, than you can from sick and miserable animals." No investigator who has tried—or been compelled to try—both will have any doubts about the truth of this statement, especially if his

comparisons have been submitted to analysis by valid statistical methods.

The number of animals used each year in the laboratories of Great Britain is probably now well over a million, mice being *facile princeps* with more than half that number, guinea-pigs second, and rats third, the figures for those species being of the order of 200,000 and 100,000 respectively. From the point of view of importance, however, both because of the work for which they are essential and because of the esteem in which they are held by the British peoples, the absolutely insignificant number of cats and dogs used annually (about 2,500 to 5.000 of each) is no measure of their relative value in teaching and research. One would therefore have supposed that special treatment would be meted out to them in this book. And so it has—but exactly in the opposite way from what might have been expected at first blush, for the authors say in essence, "Cats and dogs are so difficult that you must consult the experts (some names are given) and keep in touch with the vet. Nothing we could write here would be of any practical help to you." However, one can see behind this the shrewd tactics of the book's level-headed planners, who are willing to run with the laboratory hares in the most friendly association provided they are not also expected to hunt with the anti-vivisectionist hounds. They help to avoid this by their special deference to our domestic pets.

All the same, the book contains useful information on the maintenance—including housing and feeding—and the breeding of several important species besides the most used ones. The value of rabbits, ferrets, pigeons, and hamsters is well known, but it is not so generally appreciated that voles of several species, hedgehogs, canaries, deer mice, and cotton rats are sufficiently often required for scientific work fully to justify assigning to them severally a number of chapters in this book.

In his task of collecting, with some degree of collating, data from various experts the editor has included many excellent illustrations—of buildings, cages, equipment, normal animals—and has supplemented the chapters on individual species by some more general ones on the animal laboratory and on pest control. It would have been helpful to have included also, possibly as an additional short chapter, some discussion on "pure lines," the case for their use in research and assay work, and the best systems for producing and maintaining them. A list of available pure lines, or even of available highly inbred stocks, of mice, rats, guinea-pigs, and rabbits in this country—even if foundation breeding stock is all that can be got "off the shelf"—has never yet been compiled; it could have been, without very much additional work, by the organizers of this book and would have made it still more useful. As things are, we must wait for publication of some authoritative list by the Laboratory Animals Bureau of the Medical Research Council.

In subsequent editions—and these are pretty sure to be needed—I would suggest that some notice be taken of the fact that rats—albinos and hooded strains at any rate—can be bred in wooden cages of suitable design and that some of the healthiest and most uniform colonies here and in the U.S.A. are so raised. A reference to the use of the "dough-mixer" type of blender for preparing homogeneous diets, whether stock or experimental, might call some readers' attention to one of the most potent of all time-saving arrangements in animal diet kitchens, even for relatively small colonies. It might have been a good idea to include *Passer domesticus* in the list of pests that can bring disease to animal houses and to call attention to the corollary need for "sparrow-proof" windows and ventilators.

Two outstanding features of this book, both by the Federation's energetic chairman, Major C. W. Hume, are a chapter on "Law and Practice: the Rights of Laboratory Animals"—a brilliant and highly instructive survey of the present law governing experiments on animals—and an appendix with the modest title "A Conspectus of the Elements of Statistical Analysis." This occupies 20 pages and is a masterpiece of expository condensation. It alone is worth almost the whole of the apparently high price charged for this book. The book is indeed a bargain, and indispensable to all concerned in any way with the production and use of animals in laboratories.

MEDICAL JOURNAL

LONDON

SATURDAY JULY 2 1949

THE GENERAL AND THE SPECIAL

The title of the Presidential Address at this year's Annual Meeting reflected, in a different context, the theme of Professor Jefferson's Lister Oration. Professor Jefferson was concerned with the implications of the modern computing machines and their effect upon our ways of thinking about thinking. Dr. C. W. Curtis Bain, whose thoughtful and highly informative address appears in the opening pages of this *Journal*, discusses by detailed reference to the specialty he practises the impact of the machine on the practice of medicine. Dr. Bain develops his theme by recounting the historical steps that have led to the position of cardiology to-day. The views held at any one time on the circulation of the blood and the function of any part of the cardiovascular system are determined to a large extent by the techniques of investigation available. William Harvey, for example, was unable to fill in the gap between artery and vein because he had no microscope with which to see the capillaries. Old theories that seem to us, with modern knowledge, to have been foolish were not necessarily foolish in the setting in which they appeared, such as those of Galen on the circulation. Medicine has flagged in its pursuit of knowledge when it has clung to theories through an inert acceptance of authority, when it has allowed the theory to become a dogma, to challenge which led to professional ostracism. Vesalius and Harvey were key figures in the scientific renaissance in which medicine played a notable part. Part of their genius was the courage to follow the thought where it led them, to observe objectively, and to challenge authority without fear or favour. In their life and work they illustrated the modern theme, the independence of medicine. To-day this theme has a new variation. The new authority is not Galen; it is the State. For Medicine the State is the Minister of Health, his lay and medical Civil Servants, and the elongated shadow of the Treasury. Modern medicine is in danger of conflict with these three parts of the State mechanism.

Whatever may be the nature of this conflict, now and in the future, the strength of Medicine lies in the free advancement of knowledge, and how this, at an unequal pace, has taken place in cardiology is recounted with telling point by Dr. Curtis Bain. It might be argued that knowledge cannot advance unimpeded unless the intellectual environment is such as to liberate the spirit of inquiry. Yet the history of the forerunners of the Royal Society suggests that in the times when Milton sighed that the new presbyter was the old priest writ large the stout mind could stand out successfully against the tyranny of the ambitious politician. They excluded from their deliberations all mention of politics. But this cannot be an exact analogy. The twentieth century is not the seventeenth. The phenomenal advances of medicine are counterpoised by the growth of a spirit of political intolerance and arrogance. As an intellectual minority in the community the medical profession is subject to the pressure of the modern environment, created by demagogues who exploit the heedless impulses of the majority. Against this it can oppose the force of tradition and the advancement of medical learning. In the long run these will prevail against the febrilities of the modern political scene and the vagaries of ambitious politicians. These things cannot but obsess a hard-pressed profession, and to-day doctors are by the wish of Parliament and people caught up in the net of the politician.

Dr. Bain, like his fellow Oxonians in the seventeenth century, ignores the ephemeral, and traces the progress in cardiology that owes so much to the introduction of new instruments of measurement, from Sir John Floyer's watch in the early part of the eighteenth century to the catheter which Forssman in 1929 passed through his median basilic vein into the right auricle—and then walked to the *x*-ray department to have its shadow recorded on a film. In the interval between these two events there were the discovery of *x* rays by Roentgen in 1895; the work of James Mackenzie while in general practice; the construction of the electrocardiograph by Einthoven in 1903 and the pioneer researches of Sir Thomas Lewis; and the introduction of the sphygmomanometer. At a combined meeting of the Sections of Cardiology and Radiology this week there was much discussion on angiocardiography, another method of investigation mentioned by Dr. Bain.

The resources at the disposal of the cardiologist are now considerable, and all will agree with Dr. Bain that "the complete investigation of a patient with heart disease may therefore be a complicated affair." And he finds himself compelled to ask what will be the position of the clinician in the face of so many tests—the clinician, it is clear from the text, being in this case the cardiologist. When the specialist himself begins to feel cluttered up by the techniques of his specialty, then how much more must the general physician and the general practitioner feel at a loss in the presence of the intense specialization characteristic of modern medicine. Dr. Bain in his own specialty points the way out of the maze. As many thoughtful doctors have done before, he

emphasizes, after examining his theme, the importance of clinical examination, backed up by a selection of tests that are trustworthy. It is the clinical examination that enables the physician to synthesize his findings and knowledge, to include in this synthesis what he knows of the whole person who is his patient. Both in this country and in the U.S.A. more and more stress is laid upon this aspect of the art of medicine. And if this is true for the specialist, how much more true is it for the general physician and general practitioner. If the challenge that lies behind the title of Dr. Bain's Presidential Address is to be met, the specialist should take heed of his conclusion, and the profession at large must see to it that, however necessary specialism is, the general physician and the general practitioner hold their fundamental position in relation to the public—that of the doctor who sees the patient as a whole person in a particular setting. So long as this position is maintained the machine will not dominate medicine.

TUBERCULOUS EMPYEMA

The development of a purulent pleural effusion during the course of tuberculosis is a serious complication: unfortunately its seriousness is still not widely enough appreciated. In many cases the tuberculous infection of the pleura is one of the natural modes of termination of the disease; this is especially so in the chronic, advanced bilateral case, less often in the acute pneumonic form in which early pleural perforation occurs. Apart from these groups, in which the illness proceeds swiftly or inexorably to its fatal termination, there is a larger number of cases in which the pleural infection is less fulminant but in which the ultimate prognosis remains bad. Many of these infections occur during the course of artificial pneumothorax treatment. Apart from the serious prognosis, these cases are of great importance to-day, for the patients must remain long in hospital beds that can be ill afforded, and they also require much more individual attention than can often be easily provided. For many reasons, therefore, the efficient treatment of these patients is important: even more important is the prevention of their disability.

Though a tuberculous empyema following artificial pneumothorax treatment may occur in even the most carefully chosen and well-conducted case, the highest incidence of pleural effusion and empyema occurs in those cases in which the collapse is imperfect or contraselective: often the pneumothorax treatment should never have been started, or if started should have been abandoned at an early date. Elsewhere in this issue Dr. D. A. Andersen reports a follow-up of 74 cases of tuberculous empyema treated in Norwegian hospitals; he rightly states, "It is certainly incorrect to induce an A.P. first in practically every case, as is sometimes done on the grounds that it is an easy and safe method of treatment and therefore should be given a trial." The seriousness of the condition is demonstrated in Andersen's series: 25 of the 74 patients have died, a mortality of nearly 34%. This agrees with the findings of Woodruff,[1] who reported a series of 154 cases with a mortality of 42%, and of Brock,[2] who recorded a mortality of 44% in 90 cases.

The part that artificial pneumothorax treatment plays in tuberculous infection of the pleura has been described in a large number of papers. Morrison[3] has recently reviewed the subject, but his observation that "tuberculous empyema, although a serious complication of pneumothorax treatment, can be controlled in most patients by aspiration of the pus and re-expansion of the lung" would not be generally accepted, though he does qualify the statement by adding, "Thereafter, thoracoplasty is usually necessary." In a number of cases the state of the underlying lung, when the disease is uncontrolled, is such that it should never be allowed to expand, and primary thoracoplasty is desirable. In some it is reasonable to attempt to control the pleural infection by repeated aspiration of air and fluid and by encouraging the lung to expand. Recently, promising results have been obtained in some cases by the use of para-aminosalicylic acid, but this is unlikely to be effective when a bronchial fistula persists or the pleura is too thick and rigid to allow the lung to expand.

How long conservative treatment should be persevered with varies with personal experience and the individual case. Andersen suggests that six months is the absolute limit. Other authorities may feel that this would be far too long in many cases: the pleura has by then usually become very thick, and often sinuses have appeared at aspiration sites. If the empyema does not respond to medical measures it should be treated by thoracoplasty. When secondary infection is present a preliminary drainage is, of course, necessary. In Andersen's series 56.5% of the patients were cured or greatly improved by surgery, and he quotes the figures of Jones and Alexander,[4] who reported cure or improvement in 62.8% of 70 cases. Brock found that in his series of 90 cases of tuberculous empyema 77% of those who were treated conservatively (42 patients) died, whereas out of 48 submitted to thoracoplasty seven died (14%), the total mortality being 44%. Brock also noted that in 21 patients whose empyemata were not secondarily infected only one (5%) died after thoracoplasty. But out of 84 cases of secondarily infected tuberculous empyema 91% of the patients treated without op-

did not recover, while of the 49 treated by drainage and thoracoplasty 79% survived. In Andersen's series 14 out of 19 patients treated without operation died. There can be no question of the seriousness of the condition when treated medically, and Andersen makes a good point when he recommends thoracoplasty in those cases of persistent pleural effusion (not yet frankly purulent) which have not resolved in three months. Five cases of this type of "incipient empyema" were operated upon, with cure in all.

Thoracoplasty controls the disease in the underlying lung and is followed by the obliteration of the infected pleural space in a large proportion of cases. In secondarily infected empyemata it saves life by checking the constant purulent discharge, which sooner or later will cause amyloid disease or other toxic complications. To be effective thoracoplasty must be performed early, before the pleura has become too rigid for rapid and complete collapse to occur. Often drainage is allowed to continue for many months before thoracoplasty is begun, in the hope that the lung will expand and thoracoplasty may prove unnecessary or that a smaller space will have to be closed. Delay for these reasons is never justified, for the patient's condition always deteriorates and a poorer collapse is obtained. Thoracoplasty should be begun within 10–14 days of drainage.

Thoracoplasty can save life in many of these otherwise hopeless cases, but it often happens that a chronic discharging empyema cavity, though small, persists. Unless something is done to close it the patient is doomed to wear a tube for the rest of his life, with the constant necessity for daily dressings. The cavity may shrink down in 2–3 years and either heals or is little trouble; but usually some other form of plastic operation is needed. Andersen advises an operation of the Schede or Robert's type. Few surgeons would be eager to recommend perpetuation of the Schede type of operation to-day; there is a much greater place for plastic operations in which pleural or muscle flaps are used to produce obliteration of the residual cavity. Lam[5] writes of another method—namely, decortication of the lung—which is now being applied for the final closure of tuberculous empyema cavities. He records three cases in which healing was obtained, though in one it is doubtful if the disease was tuberculosis. His cases are few, but the method has been used sufficiently often by surgeons in this country as well as in the U.S.A. to prove that most gratifying results can be obtained. It would seem to be a dangerous or unsatisfactory procedure in tuberculous patients if used without preliminary thoracoplasty, for in many cases the lung (especially the upper part) should never be allowed to [illegible] owing to its diseased state, even if it could do so. Decortication is useful in securing obliteration of the residual infected pleural space after thoracoplasty has controlled the lung lesion and reduced the size of the empyema. When the lung fails to expand to fill the dead space it is usually because it was compressed in the early stages of the pleural effusion and held in its compressed condition by the thickened cortex. If this cortex is removed, the lung (especially the basal parts) will readily expand and fill the empyema space much more easily than would be possible by inserting large muscle grafts; often in thin patients it is difficult or impossible to obtain enough muscle tissue to fill the space completely. After decortication the skin wound can be closed, and if suction drainage is maintained for a few days healing will occur by first intention. Few things are more gratifying to a patient who has faced the dangers of a secondarily infected tuberculous empyema than to find that he has at last been rid of the tube and daily dressings that have been his lot for possibly several years.

CORTISONE IN THE TREATMENT OF RHEUMATISM

The Seventh International Congress on Rheumatic Diseases just ended in New York is likely to prove a landmark in the history of the treatment of those intractable and crippling conditions grouped under the indefinite term "rheumatism." The discovery of the adrenal hormone compound E, by Dr. Edward C. Kendall, now named by him "cortisone," and its application in the treatment of rheumatoid arthritis by Dr. Philip S. Hench and his colleagues, were recently discussed in a leading article[1] in this *Journal*. Their account of the development of this work has now appeared in the June issue[2] of the *Annals of the Rheumatic Diseases*, published by the B.M.A. The history of the treatment of any disease justifies caution in assessing the claims for a new remedy. But the world of medicine is now a ferment of ideas, experiment, and discovery, eagerly using in clinical research the new knowledge and techniques of the pure sciences. The essence of research, as Sir Edward Mellanby pointed out in his recent address[3] on Jenner, is discovery, and in the opinion of the specialists on rheumatism lately assembled in New York an epoch-making discovery has now been made in the treatment of a disease crippling in its effects and the cause of great suffering and waste of human life and effort.

The publicity which is naturally and rightly given to the almost unbelievable improvement obtained when cortisone is used to treat rheumatoid arthritis has raised

[1] *British Medical Journal*, 1949, 1, 812.
[2] *Ann. rheum. Dis.*, 1949, 8, 97.
[3] *British Medical Journal*, 1949, 1, 921.
[4] *J. Amer. med. Ass.*, 1949, 139, 1294.
[5] *New York Times*, June 1, 1949.

the hopes of countless patients, who will no doubt want to know from their doctors whether they can gain similar benefit. Unfortunately cortisone will not be available for very many months, except in small quantities to be used for further clinical trials under, it is hoped, conditions allowing for strict scientific control. Dr. Hench observed at New York that "at this stage we are not justified even to refer to our method as a treatment, except in the investigative sense." The scarcity of cortisone can be judged from the fact stated by Mr. William L. Laurence, the science correspondent of the *New York Times*, that the cost of a three-weeks course of treatment amounts to $18,000. The expense of production is certainly immense at present, and Dr. Kendall states that he and his colleagues at the Mayo Clinic are receiving only a week's supply at a time of cortisone for treating sixteen patients and of the adreno-corticotropic hormone (ACTH) of the pituitary body for treating five patients. This small supply is being carried by aeroplane each week from the Merck laboratories to the Mayo Clinic. The manufacturers are striving to speed up production,[4] but it will not be possible to increase the present small yield until 1950; even then supply is expected to fall far short of demand.[5]

Cortisone is a convenient short word for the adrenal cortical hormone, 17-hydroxy-11-dehydrocorticosterone. It was first isolated by Dr. Kendall from the adrenal cortex in 1935, and he was largely responsible for its partial synthesis, the final stages being completed by Dr. Lewis H. Sarett in the Merck laboratories. At the New York Congress Dr. Hench said that in addition to the remarkable effect in rheumatoid arthritis cortisone alleviated the arthritis associated with psoriasis and also that accompanying lupus erythematosus. Encouraging results had also been obtained in three cases of rheumatic fever. Professor Richard H. Freyberg, of Cornell University, reported good results in the treatment of Strümpell-Marie spondylitis. According to Dr. Edward W. Boland, a patient who was bedridden walked and fed herself within forty-four hours of starting treatment—"After nine days of treatment she literally danced a jig." Professor Walter Bauer, of the Harvard Medical School, from his own experience confirmed the findings of other observers. A report of the Congress will appear in a subsequent issue of this *Journal*. An account of the proceedings at the Congress was also given to the Section of Rheumatology, meeting at Harrogate this week, by Dr. G. D. Kersley. Another important point is that, because of the euphoria and increased mental capacity of those receiving cortisone, workers at the Mayo Clinic are investigating its effects on sufferers from mental disorder.

It must be stressed that in the treatment of rheumatic conditions cortisone is not a cure any more than insulin is for diabetes. Withdrawal of the hormone from a patient with rheumatoid arthritis leads to a relapse into cripple-dom. For those who want to treat this disease and for those who want to be treated it is therefore not just a question of injecting a few hundred milligrams of an extremely scarce drug in order to be cured; it is a question, so far as is known now, of being able to maintain treatment indefinitely. Both doctors and the public will therefore have to exercise great patience, relying on the skill and experience of the pharmaceutical industry to overcome the immediate problems of manufacture. If the new work now in progress is a great step forward in the treatment of rheumatic conditions, it is no less important an event in the science of endocrinology: in this field the full implications have yet to be explored.

DRUG-RESISTANT TRYPANOSOMES

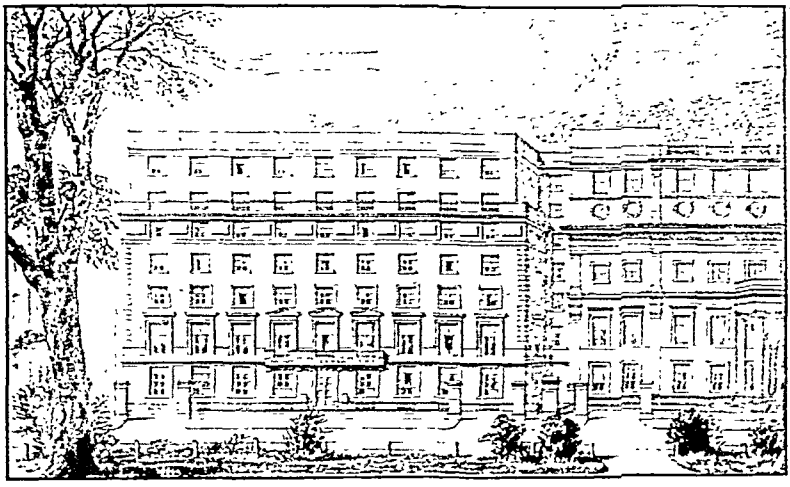
One of the great difficulties in controlling trypanosomiasis of man or animals in Africa by means of chemotherapy has been the tendency for trypanosomes to develop drug-resistant strains. In commenting[1] on the new drug "antrycide," developed by Curd and Davey for the treatment of trypanosome infections in animals, we mentioned the danger that here also resistant strains might develop. Some information about this has now been published by Wilson.[2] Working at Entebbe in Uganda, he has found that, though the soluble sulphate of antrycide cured *Trypanosoma simiae* in pigs in doses of 3 to 5 mg. per kg. of body weight, yet one pig infected with *T. simiae* and treated with 2 mg. per kg. of the relatively insoluble chloride relapsed, and attempts to cure the infection with 5 mg. per kg. were unsuccessful. In cattle also strains of *T. congolense* and *T. vivax* appear to have become resistant to antrycide, and after treatment they can resist considerably higher doses. One such strain of *T. congolense* passaged in mice was not completely eradicated by 10 mg. per kg. of antrycide sulphate, whereas a field strain obtained from an untreated cow in the same area was cured by 0.5 mg. per kg. of antrycide sulphate. The resistance had therefore increased at least twenty times.

In some cases cattle reinfected a few months after treatment with antrycide and re-treated with curative doses have developed cryptic but nevertheless fatal infections. Should such cryptic infections or prolonged latent infections occur frequently after antrycide treatment an accurate assessment of the true duration of the prophylactic effect will be difficult if not impossible. There is also some evidence to show that *T. vivax*, the other important cattle trypanosome, quickly develops a degree of drug resistance after treatment with antrycide. In animals which have relapsed or become reinfected after treatment with the drug a dose of 5 mg. per kg. will not ensure sterilization of the infection in every case and may favour the development drug resistance; a dose in excess of 10 mg. per kg. be toxic.

[1] *British Medical Journal*, 1949, 1, 63 and 315.
[2] *Nature*, Lond., 1949, 163, 873.

Toxic symptoms may develop quickly; the animal loses consciousness, and death takes place two to six hours after treatment. In other cases a severe gastro-enteritis has occurred forty-eight hours after treatment, causing death of the animal in from 6 to 12 days. Another complication reported by Wilson is that treatment with 1 mg. per kg. of dimidium bromide (phenathridinium 1553) of relapse or reinfection with strains of *T. congolense* following antrycide treatment has been unsuccessful: it appears, in fact, that strains resistant to antrycide are resistant also to curative doses of dimidium bromide. As dimidium bromide is the only other drug which has given promising results in infections due to *T. congolense*, this is a serious drawback. Whatever the actual mechanism of drug resistance, it seems likely that early treatment of relapse or reinfected cases is essential if drug-resistant cattle trypanosomes are not to be widely distributed in tropical Africa. Repeated treatments in the field three to four times a year will obviously require most careful planning and may be expensive. It will be some time before the true value of such a procedure in tsetse areas can be assessed.

LABORATORY ANIMALS



A recent attack by the *Saturday Evening Post* on anti-vivisectionists in the United States has called forth well-deserved praises from the American medical press. The dependence on animal experiments of discoveries like penicillin and tubocurarine, and of inventions like sulphathiazole and stilboestrol—to say nothing of the isolation of vitamins and hormones, such as ascorbic acid or corticosterone—is obvious to medical readers. There are, however, complex and often overlooked problems lying behind the results obtained by laboratory workers who use the whole or surviving organs of living animals as part of their laboratory equipment. Some indications of the importance of this subject is given by, amongst other things, the recent setting up of the Medical Research Council's Laboratory Animals Bureau and by the publication by the Universities Federation for Animal Welfare of a handbook on the care and management of laboratory animals; this book is reviewed on p. 20 in this issue of the *Journal*.

The Laboratory Animals Bureau is a purely co-ordinating body. It is not concerned directly with the production of laboratory animals, though in carrying out its terms of reference, which we understand to be simply that of matching "supply and demand" by directing the would-be user to the appropriate producer and *vice versa*, it may exert a very powerful influence on the numbers and kinds of animals produced, as well as on their genetic and nutritional status and their freedom from infection and infestation. In the course of this work the Bureau will have opportunities for important educational activities, and in this connexion it has already had formal dealings with senior technicians in most of the larger industrial and non-industrial laboratories producing animals, as well as unofficial contact with some of the more important breeders.

U.F.A.W. *Handbook* itself raises a number of interesting problems—one of them a question of semantics. Major Hume's invaluable introductory chapter on the miscalled "Vivisection Act"—miscalled because not one operation in ten thousand under the Act involves "live cutting"—reminds us that "the Act relates to experiments on living animals which are calculated to give pain." The use of that highly ambiguous word "calculated" may well have played into the hands of anti-vivisectionists, who are likely to use it in the sense of "intended," whereas it clearly should be read in the sense of "likely." It is much to be hoped that this troublesome word will be removed if ever the Act is amended.

The vast majority of laboratory workers using living animals under licence and appropriate certificate regard the Act as an invaluable protection, a point which was stressed by Professor Lovatt Evans in the Stephen Paget Memorial Lecture reported elsewhere in this issue. They would no more support complete absence of Governmental control in these matters, which would leave their flanks completely exposed to the not always too scrupulous attacks of anti-vivisectionists, than they would tolerate or work under conditions that apply in some parts of the United States. It is, we understand, impossible there for some pharmaceutical manufacturers to use laboratory animals whether for research or control, and subterfuges, such as the setting up of a biological institute, become necessary if any biological tests at all are to be applied to products that cannot be assayed otherwise. In this matter it would seem that our own law also might benefit from scrutiny and possible amendment. It was, after all, drawn up long before the possibility of, or indeed the need for, biological assay existed. That is no doubt why, as Major Hume points out, "The Home Secretary could not legally license painful experiments having a commercial objective." Whether the rabbit feels pain after injections of insulin is a moot point: certainly the rabbit assay of insulin has a commercial objective, though it may well have more disinterested ones besides. Surely it would not defy the wit of parliamentary draughtsmen so to reword the Act or its schedules and regulations as to free both the Home Secretary and the bio-assayist from possible embarrassment in this matter.

There are other reasons why a revision of existing legislation seems overdue. The extreme difficulties beset-ting any worker who wishes to carry out biological research or assays on curare derivatives, the restrictions on any kind of "demonstration" with living animals at meetings of learned societies, and the classifying as "operations" of many hundreds of thousands of painless injections and feeding experiments and tests are all hindrances to the rapid advance of medical science, yet in no way do the assist in giving effective protection to animals. On the other hand, there are good reasons for thinking that man rats, mice, guinea-pigs, and rabbits would be happier i Home Office supervision were extended in a suitabl manner to cover commercial and other breeding estab lishments as well as research laboratories. We believe tha most members of the Universities Federation for Anima Welfare and all members of the Research Defence Society would find common ground for constructive improvement at almost every point where the present law is a survival of vestigial precautions rather than a true and "humane" expression of modern requirements.

View of proposed new residential college.

SURGEONS HONOUR LORD NUFFIELD

RESIDENTIAL COLLEGE

The Honorary Fellowship of the Royal College of Surgeons was conferred on Viscount Nuffield on June 23.

Lord Webb-Johnson, P.R.C.S., said that it was nearly seven years since they had invited Lord Nuffield to the College in order to show their appreciation of his tremendous services to British medicine. They had then conferred on him the Honorary Medal of the College—their most exclusive emblem of merit. On that occasion their desire was to do honour to Lord Nuffield because of his remarkable gifts to British medicine. To-day the case was different. Lord Nuffield had made a gift to the College which would provide facilities and amenities unique in the world. They were therefore inviting Lord Nuffield to become one of themselves.

The room was filled, he said, with keen graduate students from all parts of the world. Lord Nuffield knew that London could provide for postgraduate medical students a wealth of opportunity that could not be surpassed; but he saw that there was one thing lacking for aspirants to high places in surgery—a residential college in the precincts of their academic headquarters. Lord Nuffield's gift would provide such a college, and students living there would make contacts with leaders of their profession which would be a stimulus to them and their pupils throughout their lives however many thousands of miles away from London they might be.

Mr. L. E. C. Norbury, Senior Vice-President of the College, introduced Lord Nuffield, saying that his name stood for generosity and progress. They were deeply grateful for all that he had done for the cause of science.

Lord Nuffield was then admitted a Fellow of the Royal College *honoris causa*.

Lord Nuffield thanked the President of the College for the honour that had been bestowed upon him, saying that in his youth he had wanted to be a surgeon, but he had had to wait until that day.

Temporary College Opened

Lord Nuffield then visited the temporary residential college and formally opened it. An account of the college appeared in the *Journal* of May 21 (p. 903). The proposed new building, which will stand next to the Royal College on the east side, is depicted above.

At the luncheon that followed, Dr. Temple Brown, one of the first residents of the college, proposed the health of Lord Nuffield, thanking him for the gift that had made the enterprise possible. This gift of £250,000 was first announced in the *Journal* of Dec. 18, 1948 (p. 1072).

Dr. S. R. Taitz, of Johannesburg, followed, and spoke of the many evidences in South Africa of Lord Nuffield's generosity. Most surgical traditions in the Commonwealth came from Britain, and it was thrilling to come to the fountainhead.

In reply Lord Nuffield said that two specialties had always particularly interested him—orthopaedics and anaesthetics. When some time ago he had suggested establishing chairs in these subjects he had been told that they were unnecessary, that every doctor was an anaesthetist and every surgeon an orthopaedic surgeon. However, all that was in the past, and these specialties were now recognized. He commented on the jealousy he had found in the medical profession, saying that it had in the past hampered him. He was pleased to see so many men there from the Dominions. The residential college would cement friendships between them to the advantage of the whole world.

CENTRE FOR INTERNATIONAL CO-OPERATION IN LONDON

THE CIBA FOUNDATION

The Ciba Foundation for "the promotion of international co-operation in medical and chemical research" was opened on June 22 at 41, Portland Place, London, W.1, by Sir Henry Dale, O.M., F.R.S. The foundation has been endowed by the firm of Ciba, manufacturing chemists of Basle. The centre will be used as a meeting-place for medical research workers and clinicians, and there is accommodation for 15 visitors. If the dignity and elegance of the foundation's headquarters are anything to go by, the work that will be done there should be of a high standard.

Speaking at the opening ceremony for the founders, Dr. Max Hartmann said that the centre had been established in London because of the pre-eminence of British research work, and because the scientific publications in the English language take first place in the world. He believed that the field of research in medicine was limitless, but team-work was essential if practical results were to be achieved. He hoped that the foundation would make practicable the interchange of views among medical scientists on as wide a scale as possible.

Lord Horder, the chairman of the trustees—the others being Lord Beveridge, Professor E. D. Adrian, and Mr. Raymond Needham—referred to the ready acceptance by the founders of a carefully worded trust deed, defining the objects of the foundation. He hoped that clinicians would play an important part in the discussions at the centre and that it would become a forum for international co-operation.

New Responsibilities

In declaring the centre open Sir Henry Dale said that it had many well-conceived and attractive features. The executive council was to be advised by a panel of distinguished scientists. He congratulated the foundation on obtaining a site so close to the centre of London's medical "quarter." He believed that there was nothing more remarkable in this scientific era than the change in the last half-century from traditional therapeutics to the ever-widening range of remedies which deal radically with the causes of disease. The production of these remedies and their proper use laid new responsibilities on doctors and chemists.

The relations between those employed in the pharmaceutical industry and those in hospital, university, and Government needed to be strengthened. An atmosphere of genuine confidence and co-operation was wanted for the develop-

therapeutic advances. Secrecy was a crippling disease of all healthy scientific activity, and he hoped that the foundation would help to maintain the tradition of international collaboration in medical science. Sir Henry thanked the founders for establishing the centre in London, and said it was appropriate that the idea should originate from Switzerland, the chosen home of the international spirit in medical activity. In conclusion, Lord Beveridge expressed gratitude to Sir Henry Dale for his encouraging remarks.

PHYSIOLOGICAL RESEARCH AND VIVISECTION

STEPHEN PAGET MEMORIAL LECTURE

The eighteenth Stephen Paget Memorial Lecture, given under the auspices of the Research Defence Society, was delivered on June 9 by Professor C. LOVATT EVANS, with Lord HAILEY in the chair.

Professor Evans, whose subject was "Physiological Research and the Vivisection Act," recalled the history of the Act of 1876. It followed upon the Royal Commission appointed during the previous year, the Commission itself being the result of the controversy ensuing upon the establishment in 1874 at University College, London, of the first chair of physiology. From the beginning it was against physiology that anti-vivisectionists directed their abuse. Physiologists had now no complaint to make about the administration of the Act in this country. Rather they welcomed it as a means of protection. It was far otherwise in the United States, where apparently any crank could demand admittance to a laboratory and create a disturbance. Another consequence of the early anti-vivisectionist agitation was the establishment, also in 1876, of the Physiological Society. Physiologists feared that since members of the Government, then as now, were mostly ignorant of science, representations made to them by prejudiced persons might lead to disastrous results in the framing or administration of the Act. The society had had a great influence on the development of physiology throughout the world, but its early work was largely concerned with the Act and with the impediments placed in the way of experiment. Five years after the Act was passed it was stated that there had been many interferences with the work on the part of the Home Office, and three particular instances were given—Fraser's work on the action of "Borneo poison," Brunton's on the treatment of snake bite, and Lister's on the arrest of arterial haemorrhage. The first prosecution was in 1882. It was that of Ferrier for work in conjunction with Yeo, only the latter having a licence. It was proved, however, that only Yeo performed the operation, and the case against Ferrier was dismissed. As in all subsequent legal actions of the kind, said Professor Evans, valuable help was given by the British Medical Association.

The lecturer went on to mention several libel and other actions, including the "brown dog" libel case, in which the late Sir William Bayliss sued the writers of a book and was awarded £2,000 damages. As a rejoinder an anti-vivisectionist later on took up two libel actions, one of which was withdrawn and the other lost. "In short, no court verdict concerning experiments on animals has ever gone against us."

The Royal Commission of 1875 was set up largely because of representations made by the medical profession, and not, as was often supposed, by the anti-vivisection societies. Another Commission was largely the result of anti-vivisectionist propaganda and did not report for six years. The conclusions of that Commission were, on the whole, in favour of the experimentalists. One paragraph in the report stated:

"... the harrowing descriptions and illustrations of operations inflicted on animals, which are frequently circulated by post, advertisement, or otherwise, are in many cases calculated to mislead the public, so far as they suggest that the animals in question were not under an anaesthetic. To represent that animals subjected to ...ments in this country are wantonly tortured would, in our ...n, be absolutely false."

...essor Evans said that it was early recognized that the ...se of physiological experiments would usually be ...ated if pain was experienced by the animal, and for that reason, if for no better one, the experimenters were careful to avoid the infliction of pain. The clamour and obstruction of the enemies of science had in no way altered the course of physiological experiment or changed its procedure, but it had made physiologists more alive to the possibility that cruelty might be perpetrated thoughtlessly.

Nowadays the control of anaesthesia had been brought to a fine art, and the latest developments in aseptic surgical technique and in chemotherapy enabled survival experiments, where these were essential, to be carried out under the conditions most favourable for the animal. Prominent among the rapidly growing branches of experimental physiology was that which dealt with human physiology. New techniques and apparatus had allowed some remarkable observations to be made on normal or diseased human subjects. None of these would have been possible without the starting-point of a large body of reliable physiological knowledge, all of which rested on the results of earlier work on animals. It was surprising to what extent this recent work had vindicated the findings of past generations of physiologists. Comparisons showed that, contrary to the assertions of anti-vivisectionist propaganda, the results of experiments on the higher animals did enable conclusions—often far-reaching ones—to be drawn regarding the physiology of man.

A vote of thanks was accorded on the motion of Major Hume, seconded by Dr. N. G. Horner. The society proceeded to reappoint its officers, and Professors J. H. Burn, H. P. Gilding, and A. A. Miles, and Dr. J. W. Trevan were added to the committee. A presentation was made to the retiring secretary, Miss Burgiss-Brown, who has served the society for thirty-eight years.

HOMES FOR AGED SICK

KING EDWARD'S HOSPITAL FUND

The Duke of Gloucester presided at the annual meeting of the general council of King Edward's Hospital Fund for L don at St. James's Palace on June 21. Referring to the Nati Health Service, the president said that there were three problems.

First, there was the steeply rising cost of the hospital se The view of the King's Fund had been set out again i annual report. The old system of accounts was ob and until departmental costing was adopted there was no means of knowing whether or not money was being used to the best advantage.

Secondly, there was everywhere a disproportion between the number of nurses needed and the numbers likely to be available—even where, as in this country, there had been a steady increase in numbers. The Fund had emphasized the need to build up a larger body of trained nurses in the hospitals. It had recently opened a residential staff college for ward sisters, and the first 24 staff nurses had just gone back to their hospitals to take up their duties as sisters. (See p. 29.)

The third problem, which was common to all countries, was the need to overhaul the administrative machinery. Progress in hospital affairs had been so rapid in recent years that everywhere, sometimes in the most unexpected places, there were to be found departments or even whole units or branches of the service which were content with methods which became obsolete thirty or forty years ago. The reception given to the Fund's memorandum on admissions and records, published last September, shows how widespread was the need for help of this kind. Out of this had come a new school for medical records officers at the Middlesex Hospital, a most welcome development into which the King's Fund had put some £7,500. The Fund was also developing a training centre for hospital caterers at St. Pancras Hospital.

A New Proposal

The Duke of Gloucester went on to describe a development of a different kind, the setting up of homes to which hospitals might send sick persons, normally over 60 years of age, for whom there was no other suitable provision. Other voluntary bodies, notably the Nuffield Corporation for the Aged, were

at work in this field, and the official services were doing what they could. But, largely as the result of first-hand experience of the Emergency Bed Service last winter, it was felt that a vigorous effort was needed to get some hundreds of beds open in homes of this kind before next winter. The Fund was therefore inviting hospitals, through their friends and supporters or through other voluntary bodies prepared to accept the responsibility, to come forward and help. The Fund was prepared within the limits of the scheme to provide the bulk of the capital needed.

The council then approved a resolution setting aside a sum of £250.000 to assist in the establishment of homes for the aged sick no longer in need of active treatment. These homes would be managed by voluntary organizations, but would be linked with the hospital service. The Fund, while providing for the capital expenditure, would rely on the Metropolitan regional hospital boards to enter into contractual arrangements with the homes for the maintenance and care of patients sent into them. Sir Ernest Pooley, chairman of the Management Committee, read the following message from the Minister of Health :

"The Minister welcomes the generous offer of the Fund to allocate £250.000 for capital expenditure for this purpose. In his view the proposal constitutes a social experiment of great value as well as being of real assistance in solving the difficult problem of the accommodation of the chronic sick in the London area."

The accounts for 1948, presented by Sir Edward Peacock, the treasurer, showed an increase in income from investments at £238,827, in part due to the addition to capital in 1948 of £425.000 from the Nuffield Trust for the special areas. Apart from legacies and other special receipts, ordinary income had exceeded expenditure by £67,710. The fact that the Fund did not spend the whole of its income in 1948 was not owing to lack of claimants but rather to the fact that in the new conditions of the hospital world it must proceed with caution. The claims made upon it were innumerable and compelling, but the Fund was anxious to concentrate on those things that were most needed and that it was best fitted to help in providing.

THE FAMILY PLANNING ASSOCIATION

NEED FOR VOLUNTARY EFFORT

The future work and position of the Family Planning Association in the light of the recommendation in the Report on the Royal Commission on Population that advice on contraception should be part of the National Health Service have been described in London by Lady Denman, D.B.E., chairman of the executive committee, and other officials of the association.

Many of the proposals in the Report are what this body has been seeking during the 19 years of its existence—it was formed in 1930 as the National Birth Control Association. It was emphasized, however, that the work of the voluntary organization will be necessary for some time to come if parents are to be advised about the planning of families, and that there was a need for a grant from the Ministry of Health for an expansion of the work of the headquarters, including the setting up of new clinics. Even when the giving of advice on contraception was undertaken by the National Health Service, said Lady Denman, there might still remain work for the association to do. Mrs. S. C. S. Robinson, the general secretary, pointed out that it would take time for a sufficient number of doctors to be trained to give advice on contraceptive methods.

Advisory Clinics

The association, the president of which is Lord Horder, has 78 branch clinics at which medical advice is given on family spacing, infertility, and minor gynaecological disorders. These clinics are situated in England, Wales, and Scotland; more are in the process of formation, and more are needed. Last year 35.000 new patients attended the clinics, in addition to persons attending for second or additional visits. A number of gynaecological disorders were discovered among the patients; these were treated at the clinic or referred to hospital. Lady Denman stated that many people did not like going to a big central hospital unless they were seriously ill, but found the association's clinics small and friendly. The association co-operates in the running of clinics in conjunction with local authorities, uring them to use their permissive powers to provide contraceptive advice to women who need it on medical grounds. Of the 145 health authorities in England and Wales, less than 60 provide clinics or special sessions at which advice on contraception is given. About 75 pay grants or fees to local Family Planning Association clinics, and several let or lend premises for use as clinics by Family Planning Association branches. The association is concerned also with providing advice and treatment for infertility, and its centre in London for the investigation and treatment of male sub-fertility is the first of its kind in this country. A centre maintained by the association in London provides the results of diagnostic tests in 24 hours.

It has been found that women prefer to receive advice from women doctors. The association arranges training sessions at clinics for doctors and also lectures for medical students and practitioners. Conferences are arranged from time to time for members of the medical profession and others. The association has standardized tests for manufacturers' goods and set up an approved list of those which have passed these tests. Further information may be obtained from its headquarters, 69, Eccleston Square, S.W.1.

B.C.G. VACCINATION

MINISTRY OF HEALTH PROPOSALS

Arrangements for introducing B.C.G. vaccination against tuberculosis in this country have been made by the Minister of Health and the Secretary of State for Scotland, and the following information has been provided by the Ministry of Health.

It has been thought advisable, since B.C.G. has yet to be tested in the conditions met with in this country, to keep the scheme within defined and suitably controlled limits. One part of the scheme will be to offer B.C.G. vaccination to all hospital nurses and to medical students as a form of inoculation, among others, to which their professional prudence may dispose them; the other part will be to make the vaccine available to chest physicians or other specialists—e.g., paediatricians—who may wish to use the vaccine on their individual responsibility in suitable cases, such as family contacts of tuberculous persons. The medical advisers of the Ministers consider it necessary, at this stage at least, that this form of vaccination should be the responsibility of physicians with specialized knowledge and experience of tuberculosis. It will consequently not be possible for anyone to obtain it by going to his own doctor, though a doctor who may consider it advisable for a particular person will, of course, be able to refer that person to a chest physician. In addition to the two schemes mentioned above, a long-term investigation to assess the value of B.C.G. in this country is contemplated.

The arrangements for giving B.C.G. to hospital nurses and medical students who wish to be vaccinated will be made through the hospitals or the authorities of medical schools, with whom the Departments will communicate about this part of the scheme. It will be a considerable task to plan and carry out these arrangements throughout the country, and it may take a long time to cover all areas.

The chest physicians who will be able to use B.C.G. within their own discretion will for the most part be among those engaged in joint service to regional hospital boards and local health authorities. Where a chest physician in this category undertakes B.C.G. vaccination he will need to do so in the capacity of his local health authority service and in association with the authority's medical officer of health, since it will come within the scope of the authority's responsibility for the prevention of tuberculosis under Part III (Section 28) of the National Health Service Act or Section 27 of the National Health Service (Scotland) Act. A circular will refer her local health authorities about the procedure to be

Supplies of B.C.G. are to be obtained from the Serum Institute, Copenhagen, from which they will be ordered by the Ministry of Health (or Department of Health for Scotland) and consigned by air weekly. The arrangements for ordering, receiving, and distributing the vaccine will be centralized in this way, because it must be used with the least possible delay after it leaves the laboratory. Instructions will be issued later about the method of ordering the vaccine. Standard forms of record have been prepared.

An exposition about principles and technique of B.C.G. vaccination has been prepared by experts for the assistance of physicians undertaking it. Two points are that it is advisable to vaccinate only persons who do not react to tuberculin, and that the vaccine to be obtained from Copenhagen is suitable only for intradermal use.

STAFF COLLEGE FOR WARD SISTERS

RESIDENTIAL TRAINING CENTRE

King Edward's Hospital Fund for London has opened in South Kensington a staff college for ward sisters. This is a residential training centre accommodating up to 26 students. The students generally have had at least a year's experience in hospital, and are seconded or nominated by a hospital which is a training school, to which they will return on completion of the course. They continue to receive their salary during the course, though not their emoluments, and no fees are charged for either tuition or residence, the whole cost being defrayed by the King's Fund.

The course lasts sixteen weeks and concentrates on three problems which face the ward sister. The first is that of imparting instruction to student nurses in the little time available for this purpose in actual hospital work. The second is that of the achievement of happy staff relations under conditions often of some stress. The third is that of administering the ward with maximum efficiency.

The emphasis is on teaching and administrative methods. The students learn different ward schedules, which they will take back with them and perhaps modify in the actual conditions of their wards. Much of the instruction is given by way of informal group discussion under the principal, Miss A. M. Downer, and the tutor, Miss C. H. S. Dobie. In addition, in the later part of the course, visits are paid to hospitals, where the students work as supernumeraries under experienced ward sisters, study the work of the almoner, the rehabilitation department, and the district nurse, and see something of personnel management. No certificate or diploma is given at the end of the course.

The college itself is in a large adapted house (formerly two houses), 147, Cromwell Road, S.W.7. The average age of the 24 ward sisters at present undertaking the course is 27. The idea behind this pioneer effort is to heighten the prestige of ward sisters' work in general, and to encourage the young trained nurse to remain in her hospital post rather than to seek some less exacting form of nursing employment. It is realized that it is in the hospital ward that the nursing shortage is chiefly felt. It seems that the idea was suggested to the King's Fund by the Ministry of Health, which, with the Ministry of Education, the Royal College of Nursing, and the Royal College of Midwives, is represented on the committee of the staff college. In time, it is hoped, many centres of this sort will be established, and this will become the normal method of training for ward sisters' posts.

The Ophthalmological Society of Egypt is offering a prize to the value of £E20 for "the most valuable contribution brought before the Annual Congress of the society." Papers should be submitted before the beginning of December. The competition open to members of the society of less than 20 years' practice. ...ge of physio may be obtained from the society, Dar ...strated if pain was ex... El Ainy Street, Cairo.

Correspondence

Medicine in the United States

SIR,—Two years ago I wrote a letter in the *Journal* (June 28, 1947, p. 949) giving some impressions of a visit to endocrine and metabolic centres in the U.S.A. Having had the privilege of a similar visit to the U.S.A. and Canada this year, I venture to express some sequential thoughts.

Of the therapeutic application of radioactive iodine I wrote, "The results are conclusively successful in exophthalmic goitre and in toxic adenoma, although the large nodular goitres with pressure symptoms are still thought more suitable for surgery." Two years' experience would permit this statement to stand, although the difficulty of exact calculation of dosage leads to a percentage of myxoedemas of the same incidence as met with after thyroidectomy; and thyrotoxic relapses follow inadequate dosage. In some centres the treatment is used on a large scale as the one of choice, and is especially favoured in recurrence of symptoms after thyroidectomy. The fear of damage to kidneys or germinal epithelium or of a carcinogenic stimulus appears to be regarded as unwarranted with radioactive iodine as distinct from other isotopes, although it is still not generally used for children or young adolescents. Clinical results are certainly impressive.

The recent treatment of rheumatoid arthritis by Kendall's compound E ("cortisone") or by the pituitary adrenocorticotropic hormone, which stimulates the adrenal cortex to produce compound E and/or compounds of similar structure, has caused a stir, and there appears to be no doubt of the dramatic clinical amelioration and of the equally dramatic fall of the sedimentation rate to normal. However, there is relapse in most cases following cessation of therapy, and the effect is regarded as a favourable influence on the normal adaptation or "alarm" mechanism of Selye in a variety of conditions rather than as necessarily specific. Apart from cost, the supply of compound E is not likely to be more than infinitesimal for some time, if ever, but the prospects of supplies of adrenocorticotrophic hormone are less depressing, even if remote.

Two years ago mineral metabolism studies still centred around sodium, but this year several years' study of potassium at the Johns Hopkins metabolic centre are coming to fruition under the able guidance of John E. Howard. It has been observed by those in contact with cases of adrenal insufficiency that excess of desoxycortone, especially with added salt, leads to excessive excretion of potassium and low serum potassium which may prove fatal. Similar potassium findings have been noted in the treatment of diabetic coma and in infantile diarrhoea. The studies at Harvard have shown similar potassium depletion after some surgical operations, particularly those associated with vomiting, diarrhoea, or gastro-intestinal drainage, and may be fatal.

Low serum potassium is rapidly detected by typical electrocardiographic changes, as well as by flame photometer. The giving of intravenous saline after operations accentuates the tendency to low serum-potassium concentration in such cases and it has been routine for some time at Johns Hopkins to add 40 to 110 milli-equivalents of potassium per day to all intravenous feeding mixtures. Since many of us were impressed by our physiological teaching that potassium in excess is a protoplasmic poison, it is perhaps easy not to be aware of the potentially fatal effects of too little potassium. A lighter side of the subject is that old-fashioned meat extracts, recommended by the Victorian doctor after operations, are found to have very high potassium content.

In my letter of two years ago I spoke of the exceptional adequate laboratory and research accommodation that I had seen, both for animal experiment and human metabolic studies. This year I saw the foundation of a 500-bed hospital where the additional planned space for investigation and research is twice that for bed accommodation. Many of us hope that in spite of initial financial stringency the National Health Service will give us such facilities in our major hospitals and that plans for the future will be courageous and made with vision. Space alone

however, does not necessarily determine good research, and there is no lack of appreciation in America of the fundamental character and high quality of research in this country, and of the clinico-pathological background on which our methods of medical education produce sound results.—I am, etc.,

London, W.1 S. L. SIMPSON.

Tuberculosis in Industry

SIR,—Dr. Stephen Hall's letter (June 11, p. 1049) on this subject raises a number of interesting points. I have heard a good deal about the inquiry into tuberculosis in the boot and shoe industry and from time to time discussed it with Dr. Alice Stewart and her colleagues (May 28, p. 926), and I think the following comments can be made.

1. The phrase "recently infected persons" was a misstatement, due to an attempt to put into different words a clumsy mode of expression which kept on recurring in the text of the MS. But, although it may well reveal some wishful thinking, in the case of this investigation we think it is perhaps not far from the truth. The observations made do *suggest*, indeed, that "transference of bacilli from one worker to another" has taken place. Final proof of this is still lacking, but more evidence in this direction will, I believe, be published later.

2. Dust conditions in boot and shoe factories are now being studied, and figures relating to air-borne bacteria will also be contained in a later report. About dust production in general, there are only two occupations in the industry where this is regarded as excessive. One is associated with a relatively high tuberculosis morbidity rate, and the operations are carried out under cover of dust-extraction plants. The other has no dust extractor and has the lowest rate of all. There may be other reasons for this difference, but the important one which strikes Dr. Stewart and her colleagues is that the former is a light job and the latter a strenuous one. Actually, the highest tuberculosis rates of all in the industry have been encountered in a strictly non-dusty light occupation, which has been found to attract an exceptionally large number of ex-tuberculous persons.

3. We should all agree that it is important for epidemiologists, as it is for clinicians, to know why some persons develop overt disease and others do not, but is it not a step in the right direction, meanwhile, to try to discover where the people are who do break down, and what they are doing?

May I say in conclusion that the findings of Drs. Stewart and Hughes indicate that exogenous reinfection and superinfection—using these terms in the strict sense in which Terplan[1] has used them—may play a considerable part in determining the incidence of the disease in the later age groups, especially in males.—I am, etc.,

Oxford. S. ROODHOUSE GLOYNE.

Resectable Carcinoma of the Stomach

SIR,—Dr. A. R. Parsons (June 18, p. 1096) quotes from a paper by me (*Brit. J. Surg.*, 1947, 34, 379), in which I stated that "of 1,405 patients with cancer of the stomach treated in the London hospitals in 1938–9, only 56 (4.03%) survived for five years." He then proceeds to compare this figure with those published by the Mayo Clinic. As this gives a wrong impression of the results of treatment in the London hospitals, would you permit me to explain that in the paper from which this quotation was taken I gave a table showing that 691 (49.2%) of the 1,405 patients were subjected to laparotomy, and in only 243 (17.3%) was resection possible? The five-year survival rate of these 243 patients was 23.1%, whereas that of the 2,772 patients who underwent resection in the Mayo Clinic was 28.9%.

Apart from an examination of the possible causes for this difference, one of the main objects of my paper was to draw attention to the fact that the figures collected by the British Empire Cancer Campaign prove that 82.7% of patients with cancer of the stomach were beyond hope of cure by the time the surgeon saw them. In the Mayo Clinic the figure was 74.5%.—I am, etc.,

London, S.W.1. W. L. HARNETT.

Abortions and Psychoneurosis

SIR,—The inquest held on the patient who died following the induction of premature labour at the 28th week by Dr. Norman Haire for mental instability and suicidal tendency (reported in the *Journal* of May 7, p. 825) raises the question of how far termination of pregnancy is justified as a treatment or prophylactic for this or almost any other variety of insanity.

Where pregnancy is the apparent cause of the anxiety state in a woman who was previously in normal mental health it seems logical, at first sight, to induce abortion. It is presumed that the removal of the cause of anxiety will be followed by a rapid disappearance of mental symptoms. But the problem is not so easy as this. However simple may be the method of induction, the operation is potentially dangerous where there is fear and deep anxiety. It is difficult to realize that nothing more than the passage of a sound to rupture the membranes or the injection of a few millilitres of a mildly irritant paste can cause fatal shock by vagal inhibition.

In the ordinary routine of hospital work where induction of premature labour is performed for, say, toxaemia, it is a commonplace to rupture the membranes or separate them by the finger above the internal os without the slightest fear or risk of causing shock. But it is a very different operation for those women who are the victims of deep depression by reason of their pregnancy, especially if it is illegitimate and has been concealed. Dr. Keith Simpson (*Lancet*, Jan. 8, 1949, p. 47) has drawn attention to the risks of interference with pregnancy. He states that of 100 fatal cases on which he made post-mortem examinations no fewer than 34 had died "immediately" after the operation—11 from vagal inhibition, 21 from air embolism, and 2 from haemorrhage.

I remember a case of early pregnancy complicated by prolonged bleeding for whom it was agreed that abortion was the correct treatment. An hour after the simple manœuvre of inserting a laminaria tent into the cervix I was alarmed, on being recalled to the house urgently, to find the woman in a state of shock, with cold sweating, pallor, feeble pulse, and clonic movements. The tent was removed immediately, and slow improvement followed. No haemorrhage or injury to the uterus had been caused by the insertion of the tent.

After the necropsy on Dr. Haire's case Dr. Keith Simpson stated at the inquest that he had found no organic disease whatever and no local injury as a result of dilatation of the cervix and injection of the paste. Here, evidently, was a case of death due to vagal inhibition in a single woman deeply depressed by reason of the pregnancy.

The indication for this operation was suicidal tendency as shown by one alleged attempt at self-destruction. And yet death was actually caused by the very measures undertaken to prevent it. Under suitable restraint in a mental home this woman could have been prevented from the risk of suicide. Modern methods of treatment of depressive states have entirely altered the prognosis for these patients and should influence our attitude to the view that if the pregnant woman attempts or even threatens suicide abortion should be induced forthwith.

It falls to obstetricians to perform the actual operation, and it behoves them to be aware of the dangers and very sure of their ground when they receive the recommendation from the psychiatrist. It should be remembered also that a number of depressed women who have had pregnancy terminated suffer from self-guilt and remorse for years afterwards. This is a factor which impedes spontaneous recovery from depression.

There are, of course, occasional cases of mental disturbance where termination of pregnancy may be indicated, but they are uncommon.—I am, etc.,

London, W.1. ALECK BOURNE.

SIR,—Can the bewildered G.P. have some guidance on the psychiatric indications for the termination of pregnancy? In my own practice I am occasionally consulted by some poor unmarried girl who is pregnant. She is invariably in the depths of despair and suffering from an acute anxiety neurosis. When I tell her that it is illegal to interfere with a pregnancy, she very often threatens suicide. In spite of my genuine feeling of pity for her the best I can offer her is to refer her to an antenatal clinic.

Am I failing in my duty in adopting this attitude? Should I refer all these cases to a psychiatrist, who might then recommend abortion? Can they then be referred to hospitals and thus avoid paying impossible fees? Or is it that psychoneurosis of a degree sufficient to justify therapeutic abortion does not occur in working-class girls, but only in those who are more affluent and on a higher intellectual level?

I pose these questions because in my ignorance I cannot distinguish the fundamental difference between my own cases and the ones about whom one reads in the Press. Perhaps some psychiatric authority would give us guidance. By this means we might even put the old lady with a hatpin out of business, relieve the hospital emergency bed service from the strain of dealing with septic abortions (by planning therapeutic abortions some time ahead), and thus save the G.P.s' time in having later to deal with the numerous gynaecological conditions resulting from unskilled interference.

In any case I think I'll send my next case to see the psychiatrist at a general hospital, particularly if she threatens suicide. I am cynical enough to doubt a conclusion agreeable to the patient.—I am, etc.,

P. R. SAVILLE.

Homerton, E.9.

Treatment of Hepatic Cirrhosis

SIR,—May I correct an error in your leading article (June 11, p. 1042) on the treatment of hepatic cirrhosis? You report the observation of Ralli, Robson, Clarke, and Hoagland[1] as recording "that parenchymatous hepatitis is associated with a fall in the antidiuretic agent normally present in the urine. . . ." In point of fact these workers reported a considerable increase in the antidiuretic potency of dialysates of urine from patients suffering from cirrhosis of the liver with ascites and peripheral oedema, when tested biologically according to the method of Burn.[2]

This increase has been confirmed by Drill and Frame[3] and more recently by Kunkel, Labby, Ahrens, Shank, and Hoagland.[4] Cases of cirrhosis in which fluid retention was not a marked feature did not excrete the antidiuretic factor greatly in excess of normal.—I am, etc.,

JAMES S. ROBSON.

Edinburgh.

*** Dr. Robson, and also Dr. F. G. W. Marson, of Birmingham, who wrote to the same effect, are correct in pointing out that Ralli and his co-workers found a rise in the excretion of the diuretic factor in cirrhosis of the liver, especially in cases with ascites. The important point, however, is that owing to disturbed liver function there is an excess of this factor, presumably due to impaired inactivation by the liver, and in consequence water is retained in the body through a process which is independent of changes in the serum protein.—ED., *B.M.J.*

Infective Hepatitis and Portal Cirrhosis

SIR,—With reference to the letter of Professor N. F. Maclagan (June 18, p. 1095), I wish to state that it was not my intention to dismiss liver function tests as useless, but to indicate that the tests specifically mentioned in my paper (June 11, p. 1032) "are occasionally unreliable in assessing the damage done to the liver." Since the point has been raised I give here the full laboratory findings in the case concerned. The readings given are the results of the tests performed two days before death.

Serum colloidal gold	000000
Thymol turbidity	2 units
Takata-Ara	Negative
Alkaline phosphatase	6 units
Serum bilirubin	32 mg./100 ml.
Serum proteins	2.5 g./100 ml.
Serum albumin	1.7 g./100 ml.
Serum globulin	0.8 g./100 ml.
Icterus index	100
E.S.R.	1 mm./hr.

Urine: Dark brown; albumin, slight cloud; urobilinogen, no excess; bile salts and pigments present. Deposits: leucine and tryosine crystals present.

There is a significant fall in serum proteins, as stressed in my previous paper (*British Medical Journal*, 1948, 1, 1079), but this fall does not occur in every fatal case. A perusal of records of fatal cases shows that the serum proteins were within normal levels with a normal albumin-globulin ratio in a few cases, while in one case the serum proteins amounted to 9.8 g. per 100 ml. four days before death.

Serum bilirubin figures provide little help in assessing prognosis. Patients with high serum bilirubin levels have recovered, while cases of chronic hepatitis with low serum bilirubin values have ended fatally. One case of chronic hepatitis had a serum bilirubin content of only 0.4 mg. per 100 ml. a few days before death. Urobilinogen estimation is of value only in early cases developing jaundice. A "battery of tests," as suggested, may reveal some abnormal values; but the mere examination of urine may give more reliable information about the impending calamity by revealing leucine and tyrosine crystals. Presence of these in urine, appearance of albuminuria for the first time during the course of illness, and the onset of delirium or coma when taken together give a reliable indication of a fatal termination.—I am, etc.,

K. DAMODARAN.

London, S.W.7.

Dried Plasma for Domiciliary Midwifery

SIR,—Dr. C. T. H. Whiteside (June 4, p. 1005) has drawn attention to the value of dried plasma in midwifery. With most of what he says I am in complete agreement. One of the most valuable lessons of the 1939–45 war was the attention it directed to the importance of early and adequate transfusion. It also served to make many of us "transfusion minded," and ever since returning to anaesthetic practice I have carried a supply of dried plasma with me in the car, and on three occasions it has proved, I am certain, a life-saving measure.

The risk of post-transfusion jaundice must be admitted. For that reason I think he goes too far when he suggests that midwives should carry the plasma and be trained to give it. The technique of transfusion is simple, but the decision when to transfuse is difficult, and is a responsibility which I feel can be undertaken only by a doctor.—I am, etc.,

REX BINNING.

Hove, Sussex.

SIR,—Mr. W. G. Mills (June 18, p. 1098) does a poor service to domiciliary midwifery in pouring cold water on the idea of intravenous therapy by the general practitioner in obstetric emergencies. While I agree with him that, preferably before shock has occurred or as soon as it has been controlled, a retained placenta should be immediately removed, nevertheless when working 30 miles from hospital, and 80 minutes from the "flying squad," the possession of plasma ready for administration and its actual administration if necessary before, during, or after the removal of the placenta are in my opinion most valuable safeguards which would hardly be neglected in hospital and therefore should certainly not be neglected on the district. By analogy, a general practitioner may give anaesthetics, but he should not give them without the same precautions (oxygen and nikethamide available) as would be taken in hospital.

In the last three years my partner and I, in the course of over two hundred confinements, have removed some eight retained placentae, and in three of these we have been very glad that we carried plasma and were able to give it in good time, and in two cases to save the "flying squad" being called at all. In another case of post-partum haemorrhage not associated with retained placenta we were also grateful for it.

It is agreed that dried plasma, because of its potential danger is not an ideal intravenous substance, but it still remains true that every practitioner who is prepared to be called to obstetric emergencies should take with him intravenous equipment. It is possible that dextran or some such substance will eventually take the place of plasma.

I could wish that Mr. Mills would join me in my plea in your correspondence columns some time ago (Dec. 13, 1947, p. 976) for the regional transfusion centres to arrange to keep general practitioners supplied with giving sets. Incidentally, a

general practitioner I have been led to understand that thiopentone can be a most dangerous anaesthetic in cases of shock.—I am, etc.,

Morpeth, Northumberland. R. P. ROBERTSON.

An Unfortunate Precedent

SIR,—Dr. B. H. Shaw says (June 4, p. 1003) that the Royal College of Physicians should not presume to meddle with professional administration. The professional administration of most of the municipal general hospitals in the country ensured, as far as such a thing is possible, that their standard of medicine could not rise above mediocrity. Was it not desirable that the Colleges and universities should use their influence to alter that state of affairs? It is a misfortune that the difficult financial position of this country is hindering the metamorphosis of these hospitals.—I am, etc.,

Tooting, S.W 17. M. WALKER.

Transfusion Compatibility Tests

SIR,—The conclusion of Dr. R. H. Malone (June 4, p. 1003) that anti-D typing of all patients prior to transfusion is essential is quite irrefutable It is also probable, however, that a tube compatibility test, using 30% bovine albumin as diluent, will prove most suitable for the busy hospital laboratory. This test is a second line of defence, which will detect incomplete anti-D antibodies, as well as the saline-agglutinating antibodies. Danger from such antibodies, as Dr. Malone points out, should be rare with accurate anti-D typing. Mistakes do occur, however, in the best regulated laboratories, as evidenced by Dr. Kidd's case (June 4, p. 1002), either due to technical or clerical errors.

A cross-matching test in tubes at room temperature and 37° C., using 30% bovine albumin as red-cell diluent, has been in use in this laboratory for some months. The tests are read after four hours as a routine measure: in the case of emergency the tubes are centrifuged after a half-hour. The test is no more time-consuming than the usual one, using saline as diluent, either to set up or to read. Technicians can quickly be taught to differentiate between rouleaux formation, which is rather marked in albumin, and true agglutination.

While agreeing that routine anti-D typing is the first essential in preparation for transfusion to avoid Rh incompatibility, I feel that this modified compatibility test is a valuable additional safeguard.—I am, etc.,

London, E.15. M. S. ROSS.

SIR,—We are in agreement with Dr. R. H. Malone (June 4, p. 1003) on the necessity of Rh grouping before transfusion, and it was not our intention to suggest that this important safeguard should be neglected. It is undertaken as a routine here, in conjunction with the slide compatibility test, in all transfusions matched by the laboratory staff. Until, however, resident blood-bank officers become sufficiently numerous, there must remain a number of transfusions where the selection of blood has to be urgently undertaken by people without laboratory experience, and it is for these occasions that we feel the albumin slide test has special value.

The justification for the routine use of the albumin slide test is that it is simple to perform and detects incompatibilities that the saline test does not. It is true that Rh antibodies in D-positive patients are rare, but in our experience their frequency has not been negligible. In each of these cases the presence of antibodies was anticipated from the history, but it is hazardous to rely on an intelligently taken history being transmitted to the laboratory. It is therefore safest to insist on the routine use of a test that can detect Rh antibodies. Where, from the history, antibodies are expected in a D-positive patient, then the more elaborate tests would, of course, be used in selecting a suitable blood.

We have never, as far as we know, been supplied with an incorrectly labelled bottle of blood, but the test could detect the bottle of Rh-positive blood incorrectly labelled Rh-negative in the case where it mattered most—i.e., when the recipient had strong Rh antibodies.—We are, etc.,

B. GODWIN.
Stoke-on-Trent. A. J. MCCALL.

Prognosis in Hysteria

SIR,—Dr. A. Barham Carter is to be congratulated on the lucid and interesting article on this subject (June 18, p. 1076) in which he describes incidentally the successful results of treating hysterical symptoms. His reference to "physicians who like to do their own psychiatric work so far as is possible" is particularly welcome; and on the strength of this one is emboldened mildly to question the assertion he makes at the outset of his conclusion that "the word 'recovery' will never mean the same to a psychiatrist as to a physician, and one can only try to correlate physical and psychological terms." Given an approach which has regard to the whole organism, is it necessary even to draw distinction between physical and psychological? Dr. Carter obviously combines in his own person the qualities of a physician with the training and experience of a psychiatrist. Should not a psychiatrist, too, be first and foremost a physician?

Explanations why an hysterical symptom disappears are certainly various. Perhaps it has served its (never fully conscious) turn. Or the hastily selected symptom may have become irksome, as instance that of blindness in the case of a young and active man, or aphonia in a naturally talkative woman. The patient may have found that his complaint does not find ready acceptance socially, or even that it results in certain sanctions, such as that of isolation, being applied. The symptom may disappear because it has been substituted by one which seems to serve the (unconscious) purpose better, and, as Dr. Barham Carter well exemplifies, there is always the possibility that the patient may, by understanding on the part of his physician, be moved to behave differently, with corresponding advantages for social adjustment.

Dr. Carter's experience that ". . . more good seemed to come from listening than from talking, as patients often found a more satisfactory solution to their problems without further prompting" helps to illustrate that perhaps there is, after all, not so much divergence of aim as between physician and psychiatrist. Widely accepted, and applied with due circumspection, the principles and practice advocated in this article might go far to meet the recognized need for treatment of psychoneurosis in its milder and less chronic forms.—I am, etc.,

Liverpool. S. BARTON HALL.

POINTS FROM LETTERS

Salicylates in Rheumatic Fever

Dr. A. D. MCDWYER (Dublin) writes: Because of its practical importance one must accept with reserve the view of Rantz and colleagues—discussed in a leading article in the *Journal* (Jan. 22, p. 144)—that massive salicylate prophylaxis does not prevent the manifestations of continuing non-suppurative streptococcal disease—really mild to florid rheumatic fever. Without prophylaxis the manifestations are: elevated E.S.R., late fever, carditis, arthritis, purpura, adenitis, pneumonitis. With salicylate prophylaxis they are late fever and carditis. Of the latter, their criteria in general are flat or inverted T waves and prolonged PR interval Massive salicylates may cause (1) fever (98.6°–100° F. = 37°–37.8° C. rectal) and tachycardia; (2) experimentally, significant alterations of RST and T in standard limb and precordial leads, and abnormal prolongation of QT for given rate (because of this, further observations may well confirm its effect on the PR interval); (3) a non-specific rise or fall in the E.S.R. during therapy and a subsequent rise for 1–4 weeks after therapy ends; (4) experimentally, prevention or suppression of a rise in the leucocyte response to infection. Further, the plasma salicylate in the second week of therapy becomes unstable in the rheumatic subject, rising or falling by 50% on constant dosage, needing an alteration in latter. Does this explain the appearance of subcutaneous nodules when the patient is "saturated" with salicylates? . . . One interesting point emerging from the incidence of the above manifestations is that their incidence of 19.6% is approximate to the estimated incidence of rheumatic fever, etc., in the community at large. The post-mortem statistics of the incidence of mitral stenosis in the general population understates the occurrence of valvulitis, a better test of which would be vascularized but otherwise normal valves—the normal human heart valve is avascular, a point completely ignored in the pathogenesis of septic endocarditis—if allowance is made that other viral diseases such as infectious mononucleosis, can cause valvulitis.

Obituary

SIR THOMAS HOUSTON, O.B.E., M.D.

Sir Thomas Houston, the doyen of the medical profession in Northern Ireland, died on June 21 in his eighty-first year. Until a few days before his death his mind remained receptive of new ideas, his interest in medical science and in current events continued unabated, and his affection and friendship for junior members of the profession maintained his youthful outlook.

Tom Houston was a son of the manse; his father and both of his grandfathers were ministers of the Reformed Presbyterian Church. Born in the Route, close to the rocky coast of North Antrim, he was one of a family of eleven, and received his early education at Coleraine Academical Institution. He entered Queen's College, Belfast, and took his B.A. in 1890, and five years later graduated M.B., Ch.B., B.A.O., with honours, proceeding M.D. in 1899. He won the coveted studentship in pathology of the Royal University of Ireland, and was a research scholar of the British Medical Association in 1902. He was a past president and an honorary fellow of the Ulster Medical Society, and a member of the Pathological Society of Great Britain. In 1937 he was president of the Section of Pathology, Bacteriology, and Immunology at the annual meeting of the B.M.A. He had twice been vice-president of the same Section in earlier years.

After filling the usual junior posts in a teaching hospital Houston was appointed assistant gynaecologist to the Royal Victoria Hospital, Belfast. Even in those early days, however, his main interest was in laboratory and research work. The appointment of Professor Lorrain Smith to the chair of pathology in Belfast, and the close friendship which had developed with Sir Almroth Wright and his colleagues at St. Mary's Hospital, turned Houston's footsteps into the path of clinical pathology. He was the pioneer worker on haematology and applied bacteriology in Northern Ireland, and year after year he stimulated in younger men a love of pathology. Early in his work he recognized the hereditary and familial tendencies of Addison's anaemia and the importance of the chronic carrier of typhoid bacilli in the urine. During the severe outbreak of cerebrospinal fever in Belfast in 1908 he and J. C. Rankin grouped the different types of meningococci. He applied a modification of Wright's opsonic technique in the serological diagnosis of the disease.

Houston was appointed physician in charge of the department of haematology and vaccine therapy in the Royal Victoria Hospital. He was for many years lecturer in toxicology in Queen's College, Belfast. He was also interested in tuberculosis and was physician to the Forster Green Hospital. During the first world war he acted as physician in charge of the medical wards and of the laboratory in the St. John Ambulance Brigade Hospital at Etaples. While studying an epidemic of trench fever he became interested in the enterococcus, an interest he maintained to the end of his life. It is unfortunate that this work of his has never been published, for he had accumulated a vast store of information about this organism, its reaction to its environment, and its possible pathogenic properties. Houston, however, was always hypercritical of his own work. For his services in the war he was mentioned in dispatches, awarded the O.B.E., and made an Esquire of the Venerable Order of St. John of Jerusalem, of which Order he was later appointed a Commander. He was knighted in 1927 for his services to medical science in Northern Ireland. In 1941 the Senate of the Queen's University elected him Pro-Chancellor.

Long after his official connexion with the Royal Victoria Hospital had ended Sir Thomas continued to occupy his usual seat in the laboratory; he was there only a few weeks ago. The memory of the familiar figure at his bench will be preserved by his portrait in oils painted by Mr. Frank McKelvey, which was presented to Sir Thomas last year by his colleagues of the hospital staff. It will hang near the laboratories he loved so well and served so faithfully for over fifty years. Sir Thomas Houston was the most modest of men. He shunned publicity in every form, he was without guile, and he was continually implicated in conspiracies of kindness. While in active practice he was first choice when illness entered a doctor's house. Many medical homes in Ulster have cause to remember him with affectionate gratitude. A quotation frequently on his lips was from the precepts of Hippocrates: "Where the love of man is, there also is love of the Art." No happier epitaph could be found for Sir Thomas Houston.

J. F. O'MALLEY, F.R.C.S.

Mr. J. F. O'Malley, who died at Bexhill-on-Sea on June 22 at the age of 80, came of a family of doctors. One of his brothers is professor of surgery and another professor of ophthalmology at University College, Galway, while yet another was in practice in London.

John Francis O'Malley qualified at Dublin in 1895, when he was first scholar, and went into general practice in London. He was early attracted to oto-laryngology, however, and after studying in Vienna he took the F.R.C.S. in 1910. He was appointed aural surgeon to the Evelina Hospital and later to the Hospital of St. John and St. Elizabeth and to the Royal Ear Hospital. On the amalgamation of the Royal Ear Hospital with University College Hospital in 1919 O'Malley became surgeon, and subsequently consulting surgeon, to the ear, nose, and throat department of University College Hospital. In the war of 1914–18 he was ear, nose, and throat specialist, with the rank of Major R.A.M.C., at the Royal Herbert Military Hospital, Woolwich, and was mentioned in dispatches.

At annual meetings of the B.M.A. in 1926 at Nottingham and in 1933 at Dublin O'Malley was vice-president of the Section of Oto-Rhino-Laryngology and in 1932–3 he was president of the Section of Otology of the Royal Society of Medicine. In 1933 he was made an honorary M.Ch. of the National University of Ireland.

O'Malley was interested in all branches of his specialty. He wrote on otosclerosis and arthritis deformans, deprecated the excessive employment of the radical mastoid operation in middle-ear suppuration, and carried out extensive researches on the ventilation of the nasal sinuses, emphasizing the importance of re-establishing air currents. He was a keen golfer, a past president of the Irish Medical Golfing Society, and a hospitable member of the old Sports Club, but his chief interest and hobby was his work, and he was in consulting practice for many years in Upper Wimpole Street. A great favourite with the Irish community in London, O'Malley was always genial, tolerant, and kind-hearted, and he will be remembered as a sound and skilful oto-laryngologist.

DR. WILLIAM ALAN BLOMFIELD, the leading oto-laryngologist of Auckland, New Zealand, died of heart disease on May 16 in hospital at Sydney at the age of 51. Born at Takapuna, the son of a well-known New Zealand journalist, Dr. Blomfield was educated at Auckland University College and at Otago University, where he graduated M.B., Ch.B. in 1923. He then

spent four years in the postgraduate study of diseases of the ear, nose, and throat at Vienna, Birmingham, and London, where he was clinical assistant at the Metropolitan Ear, Nose, and Throat Hospital. He continued his postgraduate studies in Edinburgh, taking the F.R.C.S.Ed. in 1927. On his return to New Zealand he was appointed to the ear, nose, and throat department of Waikato Hospital, Hamilton, and subsequently to the Auckland Hospital. Keenly interested in his specialty, he visited clinics in the United States and England in 1937–8. He also took his full share in the life of his community, was a prominent member of the Rotary and other clubs, and honorary surgeon to the local Jockey Club and the Boxing Association. A charming personality, always ready to extend a helping hand to his juniors, Dr. Blomfield's untimely death is a great loss to oto-laryngology in New Zealand. He is survived by his wife, a daughter, and two sons, to whom the sincere sympathy of his colleagues and friends will be extended.

Medical Notes in Parliament

NURSES BILL

When the Nurses Bill was considered on Report in the House of Lords on July 21, Lord SHEPHERD said he believed that the measure was now an agreed one. He moved to leave out Clause 4 as it stood, and to substitute the original clause.

In committee, Lord Luke had carried an amendment to delete the clause and to substitute one which took away the authority of the General Nursing Council and the Standing Nurse-Training Committees over expenditure, and transferred that authority to a new independent body. Ministers had attempted to reach an accommodation on the matter so that the Bill could be sent to the House of Commons as an agreed measure. As a consequence of the discussions a series of amendments were to come before the House that day. He recommended the House to delete the present Clause 4 and put back the original clause, and then to meet the views of Lord Luke by creating in the General Nursing Council a Statutory Committee for administering the funds for training nurses. The Bill also provided that when disputes on matters of finance arose in the Standing Nurse-Training Committees there should be an appeal to the General Nursing Council, with whom the final word would rest. The Government believed that it now possessed means by which the 600 schools which existed to-day for training nurses could, through the Standing Nurse-Training Committees, be brought into intimate contact with the General Nursing Council.

Lord LLEWELLIN thought this was a better method than the amendment which his friends had previously inserted in the Bill. He hoped that when the General Nursing Council set up the Finance Committee they would take advantage of the proposal under the first schedule whereby the Minister was to appoint three persons with knowledge of hospital administration and finance. He advised the House to accept this compromise.

Lord WEBB-JOHNSON said the amendment carried on the committee stage had been carried because of anxiety about the position of the teaching hospitals. He felt that anxiety would be removed by the amendments standing in the name of Lord Shepherd.

The House agreed to Lord Shepherd's amendments and to the deletion of Clause 7 (Expenses of Hospital Grants Committee) and the insertion of the following new clause:

(" .—(1) The Council shall appoint a finance committee consisting of members of the Council.

(2) The number of members of the finance committee and their term of office shall be such as may be prescribed by rules made by the Council under subsection (1) of section three of the Act of 1919.

(3) Any matter relating to the discharge by the Council of their functions with respect to the defraying of expenses incurred by standing nurse-training committees shall stand referred to the finance committee and any other matter may be referred by the Council to that committee; and the committee shall consider the matter and report upon it to the Council, and the Council, before taking any action on the matter, shall, unless in the opinion of the Council the matter is urgent, receive and consider the report of the committee.

(4) The power of the Council under paragraph (*f*) of subsection (1) of section three of the Act of 1919 to make rules for authorizing the delegation to committees of the powers of the Council and for regulating the proceedings (including quorum) of committees shall be exercisable in relation to the finance committee.")

On Clause 9 Lord SHEPHERD moved amendments at the request of the General Nursing Council to make it perfectly clear that no nurse trained abroad who had failed to pass an examination forming part of her training should have any title to be admitted to the register. He added that his amendments would not preclude the admission of nurses who had completed training which did not involve the taking of an examination but which the General Nursing Council could regard as satisfactory.

Lord SHEPHERD moved to insert in Clause 10 an additional provision:

"(3) No request under the last foregoing subsection shall be made by the Council with respect to the supplementary part of the register containing the names of nurses trained in the nursing and care of persons suffering from mental diseases unless the Council are satisfied that means exist whereby members of the public can readily ascertain whether a registered nurse has been so trained and no such request shall be so made with respect to the supplementary part of the register containing the names of nurses trained in the nursing of sick children unless the Council are satisfied that means exist whereby members of the public can readily ascertain whether a registered nurse has been so trained."

He said that during the committee stage Lord Webb-Johnson had expressed fears about the position of specialized training. The Government had gone closely into the matter and had produced a new subsection which it hoped would meet the difficulty. They desired in particular to make it clear that the training of sick children's nurses was not to be discontinued. Nothing in the Bill would prevent the General Nursing Council in keeping its register from attaching to the names of registered nurses the special qualifications which they had earned. The Council would have among its members representatives of specialized nurses who would watch these matters.

Lord WEBB-JOHNSON thought the new subsection would safeguard the position of the General Nursing Council. The House agreed.

On the First Schedule Lord SHEPHERD said the Minister had agreed to submit amendments one of which added to the General Nursing Council three persons who would appear to the Minister "to have had experience in the control and management of hospitals." A further amendment was also approved providing for regional elections if in the opinion of the General Nursing Council they appeared desirable. Further drafting amendments were made and the Report Stage concluded.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

J. A. R. Miles, M.B., B.Chir., has been reappointed Huddersfield Lecturer in Special Pathology, and G. W. Harris, M.D., University Lecturer in Physiology, from Jan. 1, 1950, with tenure to the retiring age, and D. B. Cater, F.R.C.S., University Demonstrator in Pathology for five years from Jan. 1, 1950.

The following medical degrees were conferred on June 11:

M.D.—D. H. Davies, M. W. W. Wood, A. G. Marshall, Marjorie Lawton.

M.B., B.Chir.—Joan C Owen.

M.B.—Phyllis L. Broomhead (by proxy).

In the *Journal* of June 4 (p. 1014) we incorrectly announced that certain honorary degrees were conferred on May 2. On that date *proposals* for the conferment of the degrees were approved. It is expected that they will be *conferred* at a special Congregation to be held on Aug. 20, when the First International Congress of Biochemistry will be held at Cambridge.

The following candidates have been approved at the examination indicated:

FINAL M.B.—*Part I (Surgery, Midwifery, and Gynaecology)*: A. G. Ackerley, L. J. H. Arthur, M. J. Ball, J. L. R. Barlow, R. G. Beard, D. A. A. Beardsmore, I. F. Bishop, P. E. Bodkin, G. H. Bond, E. C. A. Bott, S. D. Bradley, H. H. Broadhead, E. A. Cooper, M. B. S. Cooper, H. M. C. Corfield, G. A. Court, E. M. D. Craig,

S. J. Crews, Gwenllwyfar Davies, G. H. J. Dickinson, M. V. Doherty, R. E. Elvan, L.-D. Edelcamp, J. W. H. Elder, P. Elliott, G. R. C. Fisher, E. H. R. Ford, D. C. H. Garrod, T. M. D. Gimlette, J. R. Glover, A. Gol, M. P. Goodson, J. D. J. Havard, J. F. Hort, M. J. Hunter, M. M. Ives, E. W. P. Jones, A. K. Knowles, A. S. Law, J. Lynfield, D. H. Mackenzie, I. R. McWhinney, J. L. Milligan, A. O'Brien, D. J. D. Perrins, J. H. Rack, K. F. Robinson, W. Rodger, H. Schlossmann, J. B. Self, R. C. Shepherd, J. T. B. Stewart, R. Thomas, P. D. S. Thomas, P. R. Thompson, J. D. W. Tomlinson, J. F. Trunchion, E. Veldhuyzen, M. P. Ward, R. G. Watkinson, R. H. R. White, B. F. Whitehead, H. B. L. Williams, N. W. H. Young.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Professor D. W. Gordon Murray, F.R.C.S., will deliver the Moynihan Lecture at the College (Lincoln's Inn Fields, London, W.C.) on Tuesday, July 5, at 5 p.m. His subject is "The Surgery of Congenital Heart Disease."

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications (uncorrected) of poliomyelitis and polio-encephalitis together increased from 19 in the week ended June 11 to 38 in the week ended June 18. Counties with more than one case were London (6), Devon (4), Lancaster (2), Middlesex (3), Southampton (2), Surrey (2), Sussex East (5), Yorks W. Riding (5). In the week ended June 25 groups of cases were reported from Newhaven, Lewisham, Plymouth, and Cornwall. Thus it appears that the small increases so far reported are widely scattered.

Discussion of Table

In *England and Wales* infectious diseases were less prevalent during the week and there were decreases in the notifications of measles 524, whooping-cough 372, scarlet fever 152, acute pneumonia 77, dysentery 46, and diphtheria 12. Exceptions to the general decline were increases in the incidence of para-typhoid fever 17 and typhoid fever 5.

The largest falls in the notifications of measles were London 282, Middlesex 131, Lancashire 114, and Essex 101; the largest rises were Kent 182, Derbyshire 98. The largest decreases in the notifications of whooping-cough were Lancashire 111 and Middlesex 54.

A small decrease in the incidence of scarlet fever was reported in most areas; the largest fall was Cheshire 32. Notifications of diphtheria again reached a new low record, being 6 below the previous lowest figure. The chief feature of the returns for diphtheria was an increase of 7 in Birmingham C.B.

Of the 24 cases of paratyphoid fever 15 were notified in the county of Durham (Hebburn U.D. 5 and Jarrow M.B. 5). The decrease in dysentery was due to the experience of Lancashire, where the notifications fell from 67 to 17 (Oldham C.B. 6 and Liverpool C.B. 8). There were 94 cases of food poisoning notified from Southampton, Fareham, U.D.

In *Scotland* an increase of 119 was reported in the notifications of measles and there were decreases in the incidence of acute primary pneumonia 21 and diphtheria 14. The chief centres of dysentery were in the cities of Glasgow 34 and Dundee 5. Of the 26 cases of diphtheria 17 were notified in Glasgow.

In *Eire* there were decreases in the notifications of whooping-cough 88, measles 19, diarrhoea and enteritis 13, and scarlet fever 9. In contrast to the remainder of the country an increase of 30 in the notifications of measles was recorded in Dublin C.B.

In *Northern Ireland* decreases were recorded in the notifications of measles 13 and whooping-cough 10. The largest outbreak of ringworm in recent years in the British Isles has been reported from County Down. Since last September 395 children in the Newtownards area have been affected.

Week Ending June 18

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 930, whooping-cough 2,253, diphtheria 82, measles 9,152, acute pneumonia 426, cerebrospinal fever 22, acute poliomyelitis 35, dysentery 57, paratyphoid 38, typhoid fever 8.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 11. [No. 23

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales, Eire, and Northern Ireland.

Medical News

Friends of Canterbury Cathedral

A service dedicated to the science and art of healing was held at the annual festival of the Friends of Canterbury Cathedral on June 25, the arrangements for which were described in the *Journal* of April 9 (p. 630). Representatives of the B.M.A., the Royal Colleges, and medical and nursing services were present. Lord Webb-Johnson, P.R.C.S., read the lesson, and Lord Moran, P.R.C.P., gave the address. After speaking of the achievements of medicine in its conflict with diseases of the body, Lord Moran said he could tell no such tale of triumph when physicians had tried to follow the working of the mind and its many aberrations. People had not acquired the art of living together. That was the crucial problem which confronted society. They were all fumbling for a solution. Why was the worker so often without interest in his job? Was it because he was doing the wrong job? The gulf between the worker and the rest of the nation was more dangerous than any gap in our economy. The forgotten art of living together had to be relearnt over the world, and there was great need of tolerance.

Special Diets for Invalids

On the recommendations of the Food Rationing (Special Diets) Advisory Committee the Ministry of Food has made the following rationing arrangements for invalids. *Hepatitis, acute infective hepatitis (catarrhal jaundice), toxic jaundice.*—Meat: a maximum allowance of four rations a week (instead of three). *Hepatitis, chronic (cirrhosis of the liver).*—Meat: a maximum allowance of four rations a week (instead of three). *Hypoproteinaemia.*—Meat: a maximum allowance of five rations a week (instead of four). *Nephritis, with gross oedema and gross albuminuria (nephrosis).*—Meat: a maximum allowance of five rations a week (instead of four).—*Steatorrhoea (including coeliac disease and tropical sprue).*—Meat: a maximum allowance of six rations a week (instead of five). The butter ration will now be retained and only the margarine and cooking fats coupons will be cancelled. Formerly, all the fats coupons were cancelled. *Steatorrhoea, convalescent.*—Meat: *a maximum allowance of three rations a week instead of two.* Liquid Milk: a priority allowance of seven pints a week. Half-cream National Dried Milk: no change in the present allowance of one tin a week. Butter, Margarine, Cooking Fat: as at present, the coupons will *not* be cancelled. *Diabetes mellitus; hypoglycaemia, spontaneous.*—No change in the present allowances.

The Secretary Honoured

The University of Saskatoon, Saskatchewan, conferred the honorary degree of LL.D. on Dr. Charles Hill, Secretary of the British Medical Association, during his recent visit to Canada.

New Zealand Surgeons to Attend Paris Conference

Sir James Elliott and Mr. Rolland O'Regan, of Wellington, will represent New Zealand at two international medical conferences to be held at Paris in July. Mr. O'Regan will represent the Government at a meeting of the International Cancer Research Commission on July 17–22. Sir James will attend this conference and will also take part in an international conference on tuberculosis towards the end of July. He will represent the Tuberculosis Society of New Zealand.

Honorary Fellowship

Sir Maurice Cassidy has been elected to an Honorary Fellowship of Clare College, Cambridge.

American Honours for British Doctors

Lord Horder and Mr. Lawrence Abel were elected Honorary Fellows of the American Medical Association at its recent annual meeting. Mr. Abel has also been elected Honorary Fellow, and Dr. Cuthbert Dukes Honorary Associate Fellow, of the American Proctological Society.

Inspection of Children's Feet

A useful pamphlet on "Foot Inspection in Childhood and Adolescence" has been prepared for the Foot Health Educational Bureau by a committee under the chairmanship of Brigadier G. S. Parkinson. It is intended to assist school medical officers in examining children's feet, and emphasizes that much disability in later life is the result of uncorrected foot disorders in childhood. It includes suggestions on the examination of feet, a list of references, and a model form for recording the results of the examination. The pamphlet is obtainable from the Bureau at 121, Ebury Street, London, S.W.1.

New Medical School Gazette

The first number of a new periodical called the *Oxford Medical School Gazette* has been published. One issue will appear each term. Information may be obtained from the editor at Osler House, 43, Woodstock Road, Oxford.

British Orthopaedic Association

The following, nominated by the executive committee, were elected at the annual meeting:—*Corresponding Member:* Dr. P. G. K. Bentzon (Denmark). *Fellows:* Mr. F. C. Durbin (Exeter), Mr. J. H. Mayer (Tunbridge Wells), Mr. K. Stanger (Newcastle-upon-Tyne). *Associate Members:* Dr. J. K. Cunninghame (Wellington, N.Z.), Mr. Johnstone Dickie (Leicester), Mr. P. G. Essex-Lopresti (Birmingham), Mr. James Garden (Carluke), Mr. R. N. Grant (Truro), Mr. H. H. Kennedy (Chesterfield), Mr. A. W. L. Kessel (London), Mr. H. Keith Lucas (Liverpool), Mr. T. N. Norton (Grimsby), Dr. W. A. J. Pike (Auckland, N.Z.), Mr. C. G. Rob (Thirsk), Mr. F. H. Stevenson (Stanmore), Mr. T. E. Stoker (Cheam), Mr. G. S. Storrs (Bedford), Mr. G. I. Walley (Windsor), Mr R. I. Wilson (Exeter).

COMING EVENTS

Exhibition of Medical Photography

The Medical Group of the Royal Photographic Society is holding an exhibition of medical photography at the society's house, 16, Prince's Gate, London, S.W. from Monday, July 4, to Saturday, July 16. The exhibition will be formally opened on July 4, at 6.30 p.m., by Sir Cecil Wakeley.

Health and Tuberculosis Conference

The Second Commonwealth and Empire Health and Tuberculosis Conference will be held by the National Association for the Prevention of Tuberculosis on July 5–8 at the Central Hall, Westminster, London, S.W.1. The following discussions will be held. *July 5, 10 a.m.*: Tuberculosis as a World Problem; chairman, Sir Robert Young. 2.15 p.m.: Trends in the Modern Treatment of Tuberculosis, Including Streptomycin and P.A.S.; chairman, Sir Robert Young. *July 6, 10 a.m.*: Regional, County, and County-Borough Tuberculosis Schemes: chairman, Mr. Anthony Greenwood, M.P. 2.15 p.m.: Organization of Comprehensive Tuberculosis Schemes in British Colonies; chairman, Mr. Fred Messer, M.P. *July 7, 10 a.m.*: Psychological and Sociological Readaptation of Chronic Disease in Industry; chairman, Dr. N. Lloyd Rusby. *July 8, 10 a.m.*: Protection from Bovine Tuberculous Infection; chairman, Professor W. H. Tytler. Visits to hospitals and other institutions have been arranged to take place on July 8–11. Tickets for them may be obtained on July 5.

Middlesex County Medical Society

The Society's annual visitor's oration will be delivered by Professor Grey Turner on Friday, July 8, at 4.15 p.m. The subject will be "Encouragements in Surgery."

Royal College of Obstetricians and Gynaecologists

A lecture on "Caudal Anaesthesia" will be delivered by Professor R. A. Hingson, Associate Professor of Obstetrics, Johns Hopkins Hospital, Baltimore, U.S.A., at the Royal Society of Medicine (Barnes Hall), 1, Wimpole Street, London, W., on Thursday, July 14, at 5 p.m. The lecture is being given under the auspices of the Royal College of Obstetricians and Gynaeco-

logists, and an invitation is extended to Fellows and Members of the College and other doctors interested in the subject. Admission is by ticket only, obtainable from the secretary of the College at 58, Queen Anne Street, London, W. Tickets will be allotted in order of application.

Summer School in Health Education

The Central Council for Health Education will hold a residential summer school in health education at the School of Domestic Economy, Eastbourne, on July 28–Aug. 11 under the direction of Dr. Robert Sutherland. The school is intended for medical practitioners as well as nurses, social workers, and others interested in health education. The cost of the course, which includes board and tuition, is 15 guineas or 16 guineas, according to room. Particulars may be obtained from the Medical Adviser and Secretary, Central Council for Health Education, Tavistock House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

Monday

INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—July 4, 5 p.m., "*Some New Facts on the Painful Stump*," by Professor René Leriche (Paris).

Tuesday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., July 5, (1) 11 a.m., "*Bacterial Non-gonococcal Urethritis (Post-gonococcal)*," by Dr. A. H. Harkness; (2) 5 p.m., "*Retropubic Operations on the Prostate*," by Mr. A. W. Badenoch.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—July 5, 5 p.m., "*The Surgery of Congenital Heart Disease*," Moynihan Lecture by Professor D. W. Gordon Murray, F.R.C.S.

Wednesday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., July 6, (1) 11 a.m., "*Bacterial Non-gonococcal Urethritis*," by Dr. A. H. Harkness; (2) 5 p.m., "*Endoscopic Resection of the Prostate*," by Mr. R. Ogier Ward.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—At Royal Society of Medicine, 1, Wimpole Street, London, W., July 6, 4.30 p.m., "*Allergy: A Dermatologist's Reminiscences and Speculations*," Prosser White Annual Oration by Professor Marion B. Sulzberger (New York).

Thursday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., July 7, (1) 11 a.m., "*Abacterial Urethritis*," by Dr. A. H. Harkness; (2) 5 p.m., "*Malignant Disease of the Prostate*," by Mr. H. G. Hanley.

LONDON UNIVERSITY.—At Institute of Neurology, National Hospital, Queen Square, London, W.C., July 7, 5 p.m., "*Surgical Treatment of Myasthenia Gravis*," by Mr. Geoffrey Keynes.

ROYAL SOCIETY, Burlington House, Piccadilly, London, W.—July 7, 2.30 p.m., "*Muscular Contraction and ... hysical and Chemical Basis*," discussion to be ... A. V. Hill, F.R.S.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—July 7, 4.30 p.m., "*Psychiatry*," lecture-demonstration by Dr. D. Curran.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Hollings.—On June 19, 1949, at Warrington General Hospital, to Joan (née Eddy), wife of Dr. A. H. Hollings, a son.

DEATHS

Addis.—On June 4, 1949, at Los Angeles, U.S.A., Thomas Addis, M.D., late of Stanford Leland University.

Beveridge.—On June 13, 1949, at 44, Inverleith Place, Edinburgh, William John Morton Beveridge, M.B., B.Chir.

Braid.—On June 17, 1949, at Dunalistair, Milngarie, Elizabeth Grace Braid, M.B., Ch.B.

Cass.—On June 19, 1949, at Edinburgh, Frederick James Duncan Cass, L.R.C.P.&S.Ed., of 2, Eildon Street, Edinburgh, and late of Links Lodge, Montrose.

Connellan.—On June 16, 1949, at 65, Western Avenue, London, W., Edmund Victor Connellan, M.R.C.S., L.R.C.P.

Devers.—On June 9, 1949, Michael Devers, M.B., Ch.B.

Fischer.—On June 15, 1949, at Westwood, Crowborough, Sussex, Ernest Cotton Fischer, M.D., F.R.C.S., aged 83.

Francis.—On June 16, 1949, at 8, Langdale Road, Hove, James Bernard Chalmers Francis, M.R.C.S., L.R.C.P.

Greaves.—On June 14, 1949, Alice Mary Ley Greaves, L.M.S.S.A., of 5, Grosvenor Road, Seaford, Sussex.

John.—On June 9, 1949, at Sandon House, Stoke-on-Trent, Ambrose Hilton John, M.B., B.S., aged 73.

Jones.—On June 15, 1949, at Highfields, Hertford, Evan Jones, M.R.C.S., L.R.C.P.

Keir.—On June 12, 1949, William Wallace Keir, C.M.G., M.B., B.Ch., Surgeon Rear-Admiral R.N., retired, aged 72.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Dicoumarol and Prothrombin Level

Q.—*The required dosage of dicoumarol for patients undergoing anticoagulant therapy has to be judged by the level of prothrombin in the blood. I would like to know the range which is considered to be safe, and the correlation between prothrombin time, prothrombin index, and percentage prothrombin.*

A.—The normal prothrombin time, as measured by means of fresh Russell viper venom, ranges between 15 and 25 seconds with undiluted plasma when the usual technique is employed. Solutions of Russell viper venom are so unstable that it is always wise to measure the prothrombin time in a normal control at the same time as it is measured in the patient. When the normal time is around 20 seconds, the ideal level to be maintained in the patient is between 30 and 40 seconds. The prothrombin index is

$$\frac{\text{the normal time as measured in a control}}{\text{the prothrombin time as measured in the patient}} \times 100$$

and should be maintained between 50 and 66%. The prothrombin activity or percentage prothrombin level is worked out from a graph, which is constructed for the particular patient under consideration, by measuring the prothrombin time with varying dilutions of plasma, usually 100%, 50%, 25%, and 12.5%. The curve that results from plotting the prothrombin times against the plasma dilutions is a rectangular hyperbola, the prothrombin time being inversely proportional to the plasma dilutions; the curve can therefore be converted into a straight line by plotting the time against the reciprocals of the plasma dilutions. From this graph the patient's prothrombin time from day to day may be expressed in terms of percentage activity. Thus, if a time of 40 seconds is seen from the graph to represent the time resulting from 20% plasma dilution, it may be expressed as 20% prothrombin activity. It is usual to aim at 15 to 25% activity when administering dicoumarol.

Hypoglycaemia and Cerebral Lesions

Q.—*Are frequent attacks of mild hypoglycaemia after globin insulin likely to cause temporary or permanent cerebral damage? If so, what are the symptoms and signs, and is there any treatment?*

A.—Provided that the attacks do not cause coma, and are readily relieved when sugar is eaten, cerebral complications will not occur. Periods of coma of short duration are also unlikely to do any damage, but if lasting longer—say, six hours or more—they may cause serious damage to the brain. The less severe symptoms are: (1) loss of memory for recent events, which may gradually return; (2) mental degeneration, which may be permanent or, in the case of children, may gradually improve; (3) complete unconsciousness, which may persist for several weeks before death ensues from pneumonia or other disease. These serious complications only occur if a big mistake has been made in the dose of insulin or if the hypoglycaemia starts soon after the insulin has been injected and before any food is eaten. The hypoglycaemia which follows injection of the ordinary or quick-acting insulin is likely to be of shorter duration than that which occurs after the slow-acting globin and protamine-zinc insulins, and is much less likely to do harm.

If the patient is in coma, subcutaneous injection of 1 ml. of adrenaline, 1 in 1,000, is often efficacious in a mild case, but it is usually necessary to give glucose intravenously as soon as possible. Ampoules which contain 25 ml. of 25% glucose are convenient for this purpose, and the injection of 10 or 20 ml. will usually restore the patient to consciousness at once, but

25 g. (1 oz.) of sugar should be given by mouth as soon as the patient can swallow. If glucose in ampoules is not available, glucose or cane sugar 50 g. (2 oz.) in water can be given through a stomach tube If these methods are not effective, a drip infusion with 5% glucose in normal saline should be started, and if the patient remains unconscious 2,000 ml. a day may be needed for many days. If the patient has sustained serious damage to the cerebral cells he will need careful re-education, and considerable improvement may be brought about slowly.

Bacteriology of the Throat

Q.—*What is the normal bacteriology of the throat?*

A.—The bacteria to be found in the normal healthy throat may be divided into two groups—the resident and the transient flora. In the first group are included non-haemolytic streptococci of the *viridans* and *salivarius* types, Gram-negative diplococci of the *catarrhalis* group, slender Gram-negative bacilli of the *Haemophilus influenzae* family, and Gram-positive diphtheroids. These bacteria are present in varying numbers in the throats of most people, and, although they are ordinarily not associated with any disease process, some of them are potentially pathogenic, particularly if they have an opportunity to multiply in a *locus minoris resistentiae*. For example, if *Streptococcus viridans* gets into the blood stream after a dental extraction in a patient with damaged heart valves, it may initiate subacute bacterial endocarditis, or *H. influenzae* may act as a secondary infecting organism on the damaged respiratory mucosa after an attack of virus influenza.

In the second group are organisms which are recognized pathogens: *Staphylococcus aureus*, haemolytic streptococci, pneumococci, meningococci, and occasionally diphtheria bacilli. Most people with healthy throats do not carry these organisms continuously, but if the throats of a 100 normal people were swabbed 5 to 10 might be harbouring haemolytic streptococci, 20 to 40 pneumococci, and 2 to 10 meningococci. A month later there might be the same proportion of carriers of these organisms, but not necessarily the same carriers, as on the first swabbing. In other words, most of us are temporary carriers of these pathogens and as a rule suffer no ill effects from the transient invasion. Here again, if local or general resistance is lowered, infection with one or other of these organisms may follow. For instance, bronchial pneumonia and otitis media in infancy are often associated with pneumococcal types—for example, 6 and 19—which are found in the normal child's throat. Such infections might be called endogenous, and are due to bacteria of relatively low virulence. Lobar pneumonia in the healthy adult, on the other hand, is usually due to pneumococcal types of greater virulence and invasiveness—for example, types 1, 2, 5, and 7, which are not ordinarily found in the normal throat. Outbreaks of streptococcal tonsillitis are usually due to one particular strain of streptococcus which spreads from case to case. These are examples of exogenous infections, and it is generally accepted that the great bulk of infection occurs in this way.

Anaphylaxis to A.T.S.

Q.—*A boy of 14, presumably of allergic diathesis, suffers from typical seasonal hay-fever, for which he is undergoing a course of desensitization. About five years ago he had an injection of A.T.S. for a penetrating injury of the foot without ill effect. What is the likelihood of severe anaphylactic reaction following any further injection of A.T.S. or other serum? In the event of his sustaining injury in a road accident, how would the casualty officer in a hospital know of any potential risk in the routine administration of A.T.S., and, in view of this potential danger, what steps ought to be taken?*

A.—The likelihood of a severe anaphylactic reaction after a further injection of A.T.S. in this boy's case is very small. However, before any serum is given in future he should have an intradermal test with 0.02 ml. of the animal serum about to be used, in a dilution of 1 in 100. If this is positive, an ophthalmic test with a 1 in 10 dilution of the serum should be carried out. The tests are read in 10 to 15 minutes. It is important to test with dilutions of the animal serum and not with the therapeutic serum. If the skin reaction is negative, serum can be given by any route, but adrenaline should be easily available. If the skin reaction is positive and the ophthalmic reaction negative, intravenous therapy should be avoided until subcutaneous injections have been given safely; then, if intravenous therapy is necessary, the therapeutic serum should be diluted with saline and given slowly. Administration of an antihistamine drug—such as "anthisan" 300 mg.—should precede any injection of serum, and adrenaline should be immediately available. If reactions to both the skin and the ophthalmic tests are positive, an immediate reaction is probable by any route, and treatment with the serum of this particular animal is contraindicated. The patient should therefore be re-tested with the serum of a different animal. The boy could carry a card with such advice. Alternatively, and preferably, he could be immunized with tetanus toxoid and then carry a card similar to the one used by Unger (*Bronchial Asthma*, p. 611; Charles C. Thomas, Illinois, 1945):

> "*To whom it may concern:* This is to certify that..... is highly allergic and has received two 0.5-ml. doses of *tetanus* toxoid to prevent tetanus. In the event that he sustains an injury for which prophylactic doses of tetanus antitoxin would ordinarily be given, please inject instead 0.5 ml. tetanus toxoid. DO NOT GIVE TETANUS ANTITOXIN."

Distribution of Pain in Coronary Occlusion

Q.—*In a man of 65 severe pain developed over the occipital region and down the back of the neck to both shoulders shortly after he retired and lasted several hours. The next day the pain returned when he went to bed and persisted for several days. It now centred mainly in the back of the neck, in the right infraclavicular region, and down the right arm to the elbow; there was some paraesthesia in the left hand. Radiography revealed extensive disk degeneration between C5, C6, and C7, with marked spondylitis. Two weeks later the patient complained of dyspnoea on exertion, and an electrocardiogram revealed myocardial infarction of recent origin. Has such a distribution of pain been described for coronary occlusion?*

A.—It is possible for the pain of coronary thrombosis to occur in the distribution described, especially so in this case, in which there was cervical spondylitis. It is a very uncommon distribution for referred cardiac pain. Accessory sympathetic afferent fibres occasionally enter the cord at C5, C6, and C7. Heinbecker (*J. thorac. Surg.*, 1932-3, 2, 517) found a few such fibres at this level. The presence of advanced cervical spondylitis would more easily give rise to referred pain along the cervical nerves caused by summation of stimuli. There is the possibility in this case that the original pain was in fact due to the spondylitis or a prolapsed intervertebral disk, the coronary thrombosis occurring at the time of the dyspnoea.

Chronic Diarrhoea

Q.—*What are the likely causes of persistent loose stools in a man of 24? The condition has persisted for four years and does not respond to sulphonamide therapy or prolonged sedation with phenobarbitone. The patient is a well-nourished, apparently healthy individual with a good appetite, but of the anxious, over-conscientious, sensitive, sympatheticotonic type. There is no evidence of thyrotoxicosis, or any other abnormality apart from a mild pruritus ani and first-degree internal haemorrhoids.*

A.—The possible causes of chronic diarrhoea are innumerable, but in this patient many have been excluded by the long history; for instance, carcinoma of the colon or tuberculous enteritis would have declared itself in unequivocal terms within the period of four years. Undoubtedly the two commonest causes for such symptoms are ulcerative (non-specific) colitis and "nervous diarrhoea." Examination of the stools is essential to exclude infections with *Entamoeba histolytica* or flagellates; chemical analysis may be necessary if their appearance suggests steatorrhoea; the presence of blood and mucus will, of course, indicate colonic ulceration, but affords no clue to its nature. Radiological examination of the colon and sigmoidoscopy will be necessary before ulcerative colitis or other organic disease of the bowel can be discounted. The wording of the question suggests that this has been done, and the description of the

patient makes a diagnosis of nervous diarrhoea probable. A recent discussion at the Royal Society of Medicine (*Proc. R. Soc. Med.*, 1949, 42, 235) has been devoted to this problem, and particular stress was laid on the patient's personality in these cases.

Anaerobic Streptococci from Uterus

Q.—*Anaerobic streptococci have been isolated from a uterine swab from a patient who had a prolonged labour with post-partum haemorrhage four weeks previously. Three weeks later she still had a "slight loss." On curettage the uterus was found to contain a small amount of serous pus; retained products of conception were present, but there was only a mild degree of polymorphonuclear infiltration of the endometrium. She had a slight fever for three days after the curettage. What is the significance of the finding of anaerobic streptococci?*

A.—Organisms of all kinds, including anaerobic streptococci, can be cultured from the uterine cavity during the early days of the puerperium, and so frequently that their presence is to be regarded as normal. Some workers go so far as to suggest that they play a part in assisting the normal dissolution of fragments of decidua and blood-clot. Bacteria, and often anaerobic streptococci, have also been cultured from histologically normal uteri late in the puerperium in afebrile patients and even apart from pregnancy. The finding of anaerobic streptococci in the uterus is not necessarily serious or even indicative of pathological changes, though these organisms can be the source of major puerperal infections. In this case their continued presence late in the puerperium was no doubt favoured by the retention of necrotic placental tissue. Any infection, however, seems to have been limited almost entirely to this tissue, so that it subsided quickly when the latter was removed. A large literature exists on the subject, but two of the more recent references are: Holmstrom, E. G., and Murata, A., *Amer. J. Obstet. Gynec.*, 1948, 56, 531; Hesseltine, H. C., and Hite, K. Eileen, *ibid.*, 1949, 57, 143.

Ergotamine and Pregnancy

Q.—*Is the administration of ergotamine tartrate liable to cause abortion? A patient who has suffered from migraine for several years has been treated with ergotamine tartrate. She has now missed two periods and is presumed to be pregnant. What alternative treatment can be recommended, or is it safe to continue with ergotamine?*

A.—Unless the patient's previous history suggests a special susceptibility to abortion or premature labour, ergotamine is unlikely to have any significant effect on the uterus, and its continued administration is therefore not contraindicated. It may be found, however, that during pregnancy the attacks of migraine will become less frequent or even cease, and consequently the treatment will be unnecessary.

Sydenham's Chorea

Q.—*A girl aged 11 years suffers from mild afebrile chorea. She has no symptoms other than typical clumsy purposeless movements, and no signs of infection. In view of the mild course and the absence of any sign of cardiac involvement, is there any justification for insisting on rest in bed? Should salicylates or other drug be prescribed?*

A.—Patients with Sydenham's chorea fall into one of two clinical groups; in the first, chorea is accompanied by fever and tachycardia, evidence of active heart disease, perhaps arthritis, and certainly an elevated erythrocyte sedimentation rate; in the second group chorea is the only symptom, there are no signs of heart disease or evidence of active infection, and, in particular, the erythrocyte sedimentation rate is normal. In this second type, to which the questioner's patient seems to belong, there is no need for drugs other than sedatives. Rest in bed for three or four weeks is advisable in most patients, particularly when movements are vigorous. There is, however, no evidence that supervised activity prolongs the disease, and in the absence of other clinical or laboratory evidence of active rheumatic infection no harm comes of allowing the mildly choreic patient to be out of bed.

NOTES AND COMMENTS

Temperature at Ovulation.—Mrs. S. C. R. ROBINSON, Secretary of the Family Planning Association, 69, Eccleston Square, London, S.W.1, writes: Increasing numbers of practitioners are using monthly temperature readings in order to locate ovulation dates in gynaecological cases. It is laborious to explain the technique to patients, and the Medical Subcommittee of this Association has drawn up a printed temperature chart and instructions, which is used in some hospital out-patient departments and in private work. Possibly other practitioners might be glad to order copies from this office.

Post-gastrectomy Diet.—Dr. JOHN R. GILLESPIE (Belfast) writes: Under "Any Questions?" (May 28, p. 967) there is a serious omission in the answer given to the question about diet after partial gastrectomy. The concluding sentence says, "There is no general indication for medicines, but in some instances a vitamin concentrate and iron may be advisable." Now, before the operation the patient probably had excess of hydrochloric acid secretion. But after the operation he probably has a serious deficiency, or even total absence, of this secretion; and this deficiency should be met by prescribing a suitable dose of dilute hydrochloric acid, to be taken in a glass of water after at least one meal a day. Otherwise the patient is likely to develop severe anaemia.

Vaccine Lymph.—Dr. B. J. PECK (Plymouth) writes: With reference to the recent correspondence in the *Journal* on the expulsion of vaccine lymph from tubes, perhaps the following method will satisfy both those who feel that an attempt at asepsis should be made and those who are more lax. The apparatus consists of the rubber bulb of an ordinary eye-dropper, with the outlet narrowed down by the insertion of a small rubber bung which has had a longitudinal hole of about 1 mm. diameter bored through it and which is kept in place with a little rubber solution. (I understand that this is not an original idea, and one or two firms market a "vaccine-expeller" of much the same design.) The vaccine tube is inserted into the hole in the bung, and when required the lymph can be deposited on the skin by breaking off the exposed end of the tube and squeezing the bulb.

Pediculosis Pubis.—Dr. G. F. MAGURRAN (Exeter) writes: Your answer to the question of the most effective treatment of pediculosis pubis ("Any Questions?" May 21, p. 920) is to my mind very incomplete. I would beg to make the following observations: (1) The pediculi cling like limpets to the skin, and I do not believe that mere shaving and washing can be effective. (2) The nits and pediculi frequently spread not only over the pubic region but over the lower abdomen, all around the upper third of the thighs and the buttocks, and consequently are missed by treatment. (3) Surely clothing should be fumigated? (4) In a case of reinfestation in spite of adequate treatment there are probably other cases in the house. (5) I found during the war that two applications of benzyl benzoate emulsion, without shaving, were simple, clean, and adequate.

Pruritus.—Miss G. THOMPSON (Richmond, Surrey) writes: The article on the mind and the skin by Dr. I. B. Sneddon (March 19, p. 472) contains no reference to the work of O. H. Horrall (*Bile—Its Toxicity and Relation to Disease*, Chicago), who came to the following conclusions: (1) That pruritus is associated with a disturbed liver function; (2) that even a slight pressure on the biliary duct causes obstruction; (3) that in certain cases of persistent itching without jaundice there is a decreased ability of the liver to excrete phenoltetrachlorphthalein; (4) that a chronic case of pruritus cleared completely when bile salts were injected; (5) that drainage of the gall-bladder often gives complete relief; (6) that the most efficient treatment is to get rid of the icterus. Unless these points are borne in mind considerable injustice to some sufferers from pruritus will occur.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY JULY 2 1949

British Medical Association

ANNUAL REPRESENTATIVE MEETING, HARROGATE, 1949

The Annual Representative Meeting was held in the Royal Hall, Harrogate, on Friday, June 24, and subsequent days. Dr. E. A. Gregg (London) presided, supported by Dr. H. Guy Dain (Chairman of Council) and the other officers of the Association. The main and supplementary agenda contained 250 motions and amendments, almost the whole of which related to matters contained in the Annual and Supplementary Reports of Council, published in the *Supplement* of April 2 and of May 28, respectively.

FRIDAY, JUNE 24

PRELIMINARY

The British Commonwealth Medical Conference

The Chairman of Council, in dealing with preliminary matters set out in the Annual Report, said that during this year the first meeting of the Commonwealth Conference had taken place at Saskatoon. It was remarkable that though such an enormous distance had to be covered a representative of every member of the Commonwealth was present. Dr. Hill and he had represented the Association in the home country. A very successful conference was held. The Canadian hosts arranged a three-day programme in which practically all the important problems of medical administration as they affected Canada were put forward in the form of a number of papers, which were then discussed by other members of the Conference from the point of view of the situation in their own countries. The Conference was held in connexion with the Annual Meeting of the Canadian Medical Association which followed it, and most of the visitors stayed for the whole time of that meeting. It was a very informative experience. An enthusiastic welcome was given by the Canadians. It was proposed next year that a similar conference be held in connexion with the Australian Branches of the Association at their annual meeting in Brisbane. These international meetings were naturally expensive occasions, but the experiment had begun very well and he hoped it would be continued. The World Medical Association was meeting this year in London and had elected their own Secretary, Dr. Charles Hill, as president. The meeting would take place in October.

President, 1950–1

The Chairman of Council then proposed that Professor T. P. McMurray, C.B.E., M.Ch., F.R.C.S.Ed., be elected as President of the Association, 1950–1. He said that Liverpool in conjunction with Southport had invited the Association to hold its Annual Meeting there next year and had nominated Professor McMurray as President

The motion was carried unanimously and with applause.

National Formulary

On the question of the *National Formulary*, which was the subject of a statement in the preliminary part of the Report, Hendon asked that early steps should be taken to improve the contents and scope of the existing *National Formulary* so that it would prove of real value to those engaged in the science and art of medicine and to the public at large.

Dr. R. W. Cockshut said he was not criticizing the Committee, which had done a very good job within the limits set for it. But those limits were too narrow. The old idea of the *Formulary* in the days of National Health Insurance was rather being continued, and the idea behind the present compilation, it seemed to him, had been primarily one of cheapness. In the National Health Service they must get away from that idea as being a main consideration, though they would all agree that unnecessary extravagance must not be allowed. He felt that if the *Formulary* was allowed to continue in its present form the ultimate result on prescribing would be serious. Excellent preparations would be replaced by others less acceptable on the ground that they were cheap. When they compared this *National Formulary* with, say, Martindale, he felt rather ashamed of the former. He did not decry the good old drugs nor would he suggest the most expensive products, but he thought the idea of cheapness should be brushed aside. He made some amusing criticism of the "Notes for Prescribers," and said that if theirs was the sort of profession which needed that sort of advice about prescribing he did not think they deserved any increase in the capitation fee.

Dr. J. A. Ireland (Council) took exception to the implication in the Hendon resolution that the *National Formulary* had no real value. He considered that there was an enormous amount of good in the *Formulary*, though it was capable of improvement, and a certain number of deletions and additions might be made.

Dr. Frank Gray (Council) said that Dr. Cockshut had completely misconstrued the purpose of the *Formulary* and of the Committee which drew it up. There was no dictation here. The *Formulary* was intended to be only a help to those who cared to use it. It had been indicated in various ways that practitioners liked to have a *Formulary* for convenience, and accordingly a good deal of work had been put in in connexion with this. If they did not like it after it had been tried out for a reasonable time they had only got to say so. But to suggest that it was something from on high which limited their discretion in any way whatever was ridiculous. He also read into Dr. Cockshut's remarks a suggestion that the authority of the *National Formulary* had been used to favour commercial interests. This was an extraordinary implication. As for the simplicity of the preparations, this might help those doctors who were about to graduate from certain medical schools where simplicity was not recognized at its full value and might remind them that drugs after all were not the largest part in the treatment of the patient and that there were other things which were of more importance.

The Chairman of Council said that under National Health Insurance they had been used to a *Formulary* for a long time. Dr. Cockshut knew perfectly well that he might prescribe whatever was necessary for his patients, however expensive, and he might use or not use the *Formulary* as he wished. This *Formulary* was put forward for the use of the profession as it wished. It was sent out with no instructions whatever. He hoped the meeting would show its disapproval of the view Dr. Cockshut had taken and of the motion which Hendon had brought forward.

Dr. Cockshut said he had merely come there to say what he had thought. If a doctor's prescription rate was over the average for his area the matter would be investigated, and such investigations would lead doctors to say, "I am going to stick to the *National Formulary* in future." He therefore felt that they wanted a very much better *Formulary* than the one which had been placed before them.

The Hendon motion was adopted by a majority.

CIVIC WELCOME

At this point the business was suspended while a civic welcome was given to the Association by the Mayor of Harrogate (Councillor Mrs. M. Fisher, J.P.).

The Mayor said this was probably the proudest moment of her year of office. It had already fallen to her lot to welcome several conferences to Harrogate during her first month as Mayor and she hoped to welcome many more, but the present conference was not merely the biggest she was likely to have the pleasure of seeing in that hall, but also one of the most important that Harrogate could wish to welcome. The links between Harrogate and the medical profession were manifold. The town received its Charter of Incorporation in 1884, and in the official inquiry which led up to the granting of the charter much was made about the inability of the British Medical Association to come to Harrogate at that time because the town had no mayor. Well, they had had to wait 65 years before achieving the purpose for which they were apparently incorporated as a borough, but the occasion had been well worth waiting for. She hoped that the Association would have a useful and happy stay in Harrogate and that the meeting would be of great benefit not only to themselves but to the country as a whole. Finally, she presented to the Association a handsome banner bearing the Harrogate coat-of-arms, which she trusted would always be a reminder of a most successful conference.

Dr. Gregg, on behalf of the Association, thanked the Mayor for her very kind words of welcome. He had been asked how it was they had not come to Harrogate before and he had never been able to get an answer until the Mayor had given an explanation that morning. He did not think that Harrogate needed much in the way of advertisement. In the 65 years since its incorporation it had proved of value to many people in this country and from all parts of the world, and the Association was extremely pleased to have had an opportunity of holding this meeting in such beautiful surroundings. One of the things they would carry away most warmly in their hearts was the civic welcome. He thanked the Mayor also for the beautiful banner, which would be treasured in the Great Hall at B.M.A. House in London in company with a number of other banners from cities in which they had held their meetings.

The Mayor then retired.

NATIONAL HEALTH SERVICE

Dr. Dain's Statement

The Chairman of Council introduced the sections of the Annual and Supplementary Reports under "National Health Service."

Dr. Dain spoke as follows: This is an opportunity to review what has taken place since last July. We have now had nearly a year of experience of the Service, and that experience has been very informing and in many respects disappointing. We have found a public willing to accept the Service, ready to take advantage of the public provision to a very complete extent, and we have found, as we expected, that the provision of services is not likely to be sufficient to meet the demand. We in general practice have experienced an enormous demand for our services. We have had the disappointment of continued delay in the setting up of the final arrangement for all kinds of practice. We protested as vigorously as we could against the tarting of a service until more complete arrangements had been e, and at the end of a year we find that the Government t even yet prepared to agree the terms of service of consnts and specialists in our hospitals, and the final remuneraof general practitioners is not yet determined. That has a cause of great dissatisfaction. There is much yet to be decided, and it is not surprising that many of our members, willing and anxious to give a good service, have found themselves very handicapped in their work. We are confronted with a dangerous situation such as we had never anticipated. We assumed on the statements given to us before we accepted the Service that our entrance into the Service was conditional on the establishment of a Whitley machinery by which our terms could always be discussed and which would be backed by arbitration in the event of disagreement. Under no other conditions could we have accepted service. We could not and would not as representatives of a great profession in this country have accepted a position in which we should be placed completely in the hands of the Government or of a Government Department. If we cannot attain a complete freedom to take our case, whatever we may consider it to be, to arbitration we shall be compelled to come out of the Service. (Prolonged cheers.)

It is a great comfort to me to see the extent to which you react to this particular situation, because in my view there is no possibility of going back from this. We have gone into the Service and have hoped to make it a good one, but we can do that only if we are free to express our opinions as we are able and free to take our difficulties to arbitration, and are not subject to the ultimate decision of a Minister as to whether we may or may not make that resort.

The position, of course, is altering in the field of negotiation very materially. In the past, in the matter of Whitley Councils the Government have stood outside and watched the proceedings in a benevolent way as between employer and employed, and have approved of Whitley Councils as representing both sides of an industry. But if the Government of the country are to continue to become increasingly the employers of one section of the community after another, and are to be in our case the employers of the medical profession, they must be prepared to accept the position of employers with regard to Whitley Council machinery, and not stand behind any previous idea that the State must be outside such a situation. They cannot be employers and judges at the same time.

It is natural for the Government to say, as I understand has been said, that it cannot be in a position in which any profession or calling can dictate to the Chancellor of the Exchequer what his Budget shall be. But we cannot stand for that attitude. We must have the right to go to arbitration even though it is the Government which is the employer. It is essential to us if we are to continue in the Service that freedom to go to arbitration should never be in question. (Loud applause.)

The Amending Bill

Dr. A. W. Gardner (Brighton) called upon the meeting to register its profound dissatisfaction at the Minister's breach of faith in not honouring his undertaking to consult the medical profession before presenting the Amending Bill to Parliament. He said that they had been told that the Minister promised to consult the profession before submitting the Amending Bill to Parliament, and he had failed to do so. Members of the profession had done their best to work the Act, but they could not go on working the Act if the Minister said one thing one day and changed his mind the next.

Dr. D. F. Hutchinson (West Middlesex) said that the Minister had repeatedly made suggestions and promises, none of which had been carried out. It was only a day or so before the Amending Bill was tabled that their representatives were assured that the Association would be consulted. This had gone on for too long. They had the opportunity at the present meeting of making it perfectly clear to the Minister that these political tricks should be exposed for what they were.

Dr. W. R. E. Harrison (Brighton) appealed for a unanimous expression of dissatisfaction with the behaviour of the Ministry of Health. But words expressing dissatisfaction taken alone would cut no ice with Mr. Bevan. The time must come when such words were translated into action.

Dr. A. G. Manley (Richmond) asked that the meeting might be told when the Minister actually gave an undertaking to consult the profession as stated in the Brighton motion.

The Chairman of Council replied that the position with regard to the Amending Bill was that they had a distinct under-

standing with the secretary of the Ministry that immediately the Service started they should discuss with him the contents of the Amending Bill and learn from them what subjects it was proposed to include. That had not been implemented. There had been no consultation as to the contents of the Bill, and when they protested, the Bill having been printed and laid before Parliament, that they had not had the promised consultation, the Ministry took refuge in the position that they could not be shown the Bill before it had been presented to Parliament. But they had never asked that the Bill should be shown to them, only that its contents should be discussed. The secretary of the Ministry had said that the Ministry, having heard their arguments, regarded this as consultation on the contents of the Bill.

The Brighton motion registering profound dissatisfaction at the Minister's breach of faith in not honouring his undertaking to consult the profession before presenting the Amending Bill was carried unanimously.

Medicines for Private Patients

Dr. J. W. McCarthy (Hendon) moved that "disappointment and resentment" be expressed by the Representative Body at the failure of the Minister to include in the Amending Bill provision for the free supply of medicines and scheduled appliances for private patients. He said that it was very important to the survival of private practice that patients who elected to have a private doctor should not be penalized when they required expensive appliances and preparations. The Minister had said that he could not subsidize private practice. But, after all, everybody in this country was paying in some way or other for this Service. Admittedly the administrative difficulties would be great but they would not be insurmountable. Dr. R. Kelson Ford (Chelsea and Fulham) pointed out that it was the patient who was being penalized, not the doctor. To make a patient pay twice was almost savouring of malice, possibly of vindictiveness. Dr. A. M. Easton (Kingston-on-Thames) and Dr. A. V. Russell (South Staffordshire) supported the motion.

Dr. Dain said that they had been pressing all the time for the right of the private patient to receive medicines as part of the service. An amendment to that effect to the Amending Bill would be moved, and he hoped that representatives would do what they could with their Members of Parliament to impress upon them the public interest in this matter.

Dr. E. C. Warner (Marylebone) said that the Minister was acting quite arbitrarily in this respect, even by Parliamentary standards. Private practice in this country must be supported if they were going to survive as a free profession. Visitors to this country were told that they could have all the health benefits under the Act, and yet benefits were being denied to our own people. Mr. Bevan had said on March 15 last that there was no limitation to what the Health Service could do.

Dr. J. Lipetz (City of Edinburgh) considered that the Hendon motion was scarcely in keeping with the serious purpose of that meeting. If any private patients felt that perhaps they were getting better service by seeing doctors privately and by being willing to pay privately for their services, he thought such patients should pay also for their medicines. The administrative difficulties of providing free medicines for private patients would be considerable, but much more important was it that the principle involved would be quite contrary to the spirit of the Act. This was not a constructive proposal. He begged the meeting not to make an issue of so flimsy a point.

The Hendon motion was carried by a considerable majority.

Position of Aliens

Dr. J. C. Arthur (Gateshead) asked the meeting to express strong disapproval of the position whereby any alien has free access to all medical services paid for by the British taxpayer while the taxpayer is denied free medicine if he elects to make a private contract with his general practitioner. He said that the position was an intolerable one.

Mr. Eric Steeler (Marylebone) said that the Gateshead motion was not strictly accurate. Six months ago a patient was flown over to this country to have a specific operation performed on him by the present speaker. The patient wanted to have it done under the British Health Service. The speaker accordingly wrote to the Ministry and asked whether it could be done under that Service, and the reply was that it could not, that an alien arriving in this country for a specific operation or treatment was not entitled to the benefits of the National Health Service. He asked further what was the position of a Commonwealth citizen coming over here for a specific operation or treatment, and was told again that the answer was "No." Of course, the visitor might quite easily come over here for another purpose and while here develop an illness which required treatment. But the fact remained that any alien was not entitled to a free National Health Service.

Dr. Hill (Secretary to the Association) said that Mr. Steeler was quite correct. When they raised the original point as to whether aliens were entitled to the benefits of the Service they were advised by lawyers that they were so entitled because they came within the description of persons who were for the time being within the area of an Executive Council. Mr. Steeler's experience showed that the Ministry of Health, having achieved the legal position that all aliens in the country were entitled to the Service, had, by a process of administrative law, divided the aliens into two groups—those who came as tourists and fell ill while here, and those who came deliberately with the purpose of seeking the benefits of the Service. This was an added complication to the position.

The Gateshead motion was carried with one dissentient.

The Right to Arbitration

Dr. S. J. Firth (Brighton) moved: "That this meeting is of opinion that arbitration provided for in the Amending Bill should be under Whitley Council arrangements, and not as set out in sect. 12 of the Bill."

He said that without the consent of one or other party a trade dispute could be referred to the Minister of Labour, who would set up an independent tribunal, but the decision of that tribunal could be accepted only as advice. The argument might well be that it would be unconstitutional for a Minister to be ruled by the decision of an independent body. In terms of general policy it would be difficult to imagine that an independent body could overrule the State, but we had to-day a somewhat changed view of democracy. It was suggested that it must be considered essential to the working of the National Health Service that any dispute, certainly in regard to remuneration and conditions of service, should go to an arbitration tribunal, whose decision should be binding on both parties.

Dr. G. O. Barber (Mid-Essex Division) considered that the Minister's refusal to grant the right of appeal in disciplinary cases, or arbitration if the Whitley machinery broke down, showed an autocratic attitude which the medical profession would not tolerate.

They felt that they had been completely let down over this failure to go to arbitration. They should put it strongly that they would not tolerate his autocratic attitude. The time had come when they had to show that on this fundamental principle they were not going to tolerate the autocratic attitude of the Minister.

Dr. A. G. Manley (Richmond) held that the right of arbitration must be an integral part of the Whitley Council machinery set up for the medical profession, and must be incorporated in the Amending Bill. If the constitution of the Whitley Council machinery was made so that they could arbitrate on all matters within such machinery, then they would achieve the end which they were seeking. He submitted that Clause 12 of the Bill covered the admission of trade disputes and was not directly allocated to Whitley Council machinery, except that the disagreement might at a later date be dealt with by such machinery when set up. Their job was to ensure that the constitution of such machinery was to their liking.

Dr. R. Forbes (Hendon) said there would be some difficulty if the meeting passed the Brighton resolution in its present form—namely, that arbitration provided for in the Amending Bill should be under Whitley Council machinery and not as set out in Clause 12 of the Bill. The operation of the Whitley machinery was primarily to enable employers and employees

to come together to discuss matters of common interest and to arrive at agreement if practicable. On occasion agreement was not reached, and what they wanted to ensure was not the situation foreshadowed under Clause 12 of the Amending Bill —namely, that there might be arbitration ensuing on disagreement—but that there should be arbitration if they or the Minister so desired. Brighton was suggesting that arbitration should be incorporated in some way in the Whitley machinery. What they wanted was that the Whitley machinery should stand, but it should be backed by compulsory resort to arbitration.

Whitley Machinery

Dr. Hill (Secretary) said that Whitley machinery was a voluntary arrangement. What they were promised in terms which had been set out in the *Journal* was that voluntary arrangements would be buttressed by an arbitration system. Therefore it was necessary for something to be said in the Amending Bill as to the form of that arbitration machinery. The Ministry had always made plain to them that there would be an arbitration agreement defining the field of subjects upon which arbitration could properly be sought, but it had always been understood that whatever else came within the realm of arbitration as a result of that agreement remuneration certainly would do so. Therefore the question arose, Did Clause 12 of the Amending Bill provide what was necessary and what was promised? The effect of Clause 12 was to provide settlement by arbitration only if the Minister approved, and the Court of Inquiry if the Minister did not agree that there should be settlement by arbitration. Since seeing the Amending Bill they had been exploring the problem of whether any other method of securing arbitration existed. There was a system of arbitration under the National Arbitration Tribunal (Defence Regulations, 1940). This was a system under which one or other party could claim arbitration. With the lawyers they had been asking whether in fact, despite the unsatisfactory character of Clause 12, there was not in existence a system of which they could take advantage. Under neither system —the Industrial Court Act system nor the National Arbitration system—could there be compulsory arbitration on matters which were dealt with by regulations. Nothing could be done to interfere with the regulation-making powers of the Minister, and that brought them right up against the fundamental issue raised by the new arrangement. Remuneration would in due course be the subject of regulation; therefore a constitutional issue existed here. They had to secure a form of arbitration which provided for arbitration at the request of one or other party even though the subject were one which was dealt with under the regulation-making powers of the Minister. It was desirable to separate Whitley from the arbitration system, and in examining the arbitration system they should face the fact that there was no existing arbitration machinery which was satisfactory for their purpose. There would need to be new legislation if they were to establish a system of arbitration which could back Whitley and deal with remuneration.

Dr. C. P. Wallace (Guildford) said that the whole profession was indebted to the President of the Association, Sir Lionel Whitby, for his statement in a letter to *The Times* on the previous Monday. He had pointed out that the implications for the professional classes were grave and far-reaching. If they were to go to war with the totalitarian system they must have leadership not only from the Chairman of Council—from whom they had already received it—but from the Council as a whole.

It was agreed at this stage to pass from the Brighton resolution to a later resolution by Kingston-on-Thames which was thought to deal with the matter more fully.

Dr. T. W. Morgan (Kingston-on-Thames) accordingly moved

at as the Minister had withdrawn the official assurances and
rtakings, repeatedly given to the profession, on the ques-
f arbitration in the event of a dispute, the Representative
demanded that effective action be taken forthwith to
that arbitration machinery be set up, and that demands
bitration by the profession should not be subject to the
ter's veto.

had been said that morning that the Minister of Health bound by precedent. To a certain extent that was true, but it had also been said that in that event he could not be a party to arbitration. He submitted this was not right. They all knew that there were many cases in the Law Courts in which although the title of the case was *Rex* v. *XYZ*, the decision of the judges was against *Rex*. If this request to the Ministry for the right of arbitration which should not be subject to the Minister's veto was turned down then the only course open to them was to resign forthwith from the Service. (Applause.) They were at the parting of the ways. Either this Service was going on and they were going to become just stooges or tools of the Ministry, or else they were going to retain a certain amount of the independence of the profession.

Dr. J. A. Gorsky (Westminster and Holborn) moved a further amendment: "That this Representative Body therefore calls upon the Minister of Health to redeem his Government's pledges by the necessary alteration in the Amending Bill." He moved this amendment in the full consciousness of a constitutional crisis. When the General Medical Services Committee met the Ministry of Health to discuss the case for higher remuneration for general practitioners it learned to its dismay of the change of front regarding the provision of adequate machinery for arbitration. Dismay had now turned into disgust, and disgust into growing anger at what the profession considered a piece of political chicanery, particularly as it was quite obvious that the Ministry was fully aware of the wording of Clause 12 of the Amending Bill when it was discussing the matter with Dr. Wand and other representatives. Clause 12 applied only the existing machinery for industrial arbitration and took no cognizance of the new constitutional position created by the introduction of the N.H.S. and the national employment of the professional classes.

Within the framework of the new Service and with the increasing extension of nationalization into new fields of economic life, more and more professional workers were becoming employed directly or indirectly by the State. Medical men and women could now give the lead to all professional classes in making a firm stand for the freedom, as a right, to negotiate the terms and conditions of their service with the State as their employers, to strive, within the framework of conciliation agreement and full arbitration, for a higher standard of living and more tolerable working conditions in return for the truly efficient service rendered by them since the inception of the Act.

The profession, Dr. Gorsky continued, had made a sacrifice of freedom, giving up various rights by the virtual extinction of private practice, and in return they asked for a clear ratification of political pledges. By nationalization the Government had made itself the owner and the boss. This crystallization of political ideology had completely altered the whole aspect of the system of government and therefore changed the old idea of the prerogatives of the Crown. The Government protected itself at the expense of the citizen by using the traditional prerogative of protection of the Crown. The Government was in effect setting itself above the law. It was not now one law for the rich and another for the poor; it was one law for the Cabinet and its satellite executive and another for the citizen. After a close examination of the constitutional position Dr. Gorsky said that the prerogative was a matter of law and not of fact and so must be determined by reference to some separate enactment. Therefore he demanded as of right, and not by compulsion, that the Amending Bill should clearly enact the right to arbitration, only subject to the negotiations governing the machinery of arbitration and that of the Whitley Councils. The fact that they were paid by fees and not by fixed salary clearly wiped out the question of prerogative, and although the fees were not as yet fixed by regulation there was nothing now to prevent the Minister of Health using his regulation-making powers to alter them at will. The Lord Advocate (Mr. John Wheatley) had stated that it was the intention of the Government to set up a tribunal on the lines of the Civil Service Arbitration Tribunal. They all knew that that tribunal was limited to Civil Servants with an upper ceiling limit of £1,200 per annum. "We are not salaried Civil Servants and we hope we shall never be."

Dr. Morgan on behalf of Kingston-on-Thames accepted the addition by Dr. Gorsky.

Dr. S. Wand moved a further amendment to the Kingston-on-Thames motion—namely, to insert the words "including arbitration for resolution of disputes involving finance." He said that they were discussing here a motion making reference to arbitration, but they were apt to forget that arbitration could be arranged for a whole host of matters other than finance. When they discussed the Whitley Council machinery recently it was made quite clear to them that there could be defined a field in which arbitration would be applicable, but that that field need not necessarily involve remuneration at all. That being so, it was obviously necessary for this body to make it quite clear that they wished finance to be included in that arbitration field. They as a profession would regard compulsory arbitration as something which was fair and to which they could attach themselves.

Dr. Morgan on behalf of Kingston-on-Thames accepted this addition also.

The Kingston-on-Thames resolution with these additions was then put to the meeting and carried unanimously in the following form:

"That as the Minister of Health has withdrawn the official assurances and undertakings repeatedly given to the profession on the question of arbitration in the event of a dispute, this Representative Body demands that effective action be taken forthwith to insist that arbitration machinery (including arbitration for resolution of disputes involving finance) be set up, and that demands for arbitration by the profession shall not be subject to the Minister's veto. This Representative Body therefore calls upon the Minister of Health to redeem his Government's pledges by the necessary alteration in the Amending Bill."

Threat of Resignation

Dr. S. F. L. Dahne (Reading) called upon the meeting to advise the profession to resign from the N.H.S. unless the Minister guaranteed that in the event of disagreement between representatives of the profession and himself all matters should be submitted to arbitration, and that in the event of disagreement on the betterment factor this be submitted immediately to arbitration. He said that his motion carried the Kingston motion one step further. It put forward the constitutional issue. It would afford them the right to take direct and decisive action.

Dr. Wand asked how they were to decide at the present moment, while the Amending Bill was still before Parliament, what was the right moment to act. There had been a tendency of late to bandy about the word "resign" too lightly. When they came to the point of putting forward their resignation they wanted to be sure that at the periphery it was known just where they stood. He asked the meeting to await the final shape of the Amending Act and in the meanwhile to be satisfied with the resolution of Kingston-on-Thames.

Dr. Manley (Richmond) agreed with Dr. Wand. The Minister had not said he would not arbitrate, but he had said he would not arbitrate on certain matters without further discussion. He considered it too early to pass such a motion as the one Reading had put forward.

Dr. A. W. Gardner (Brighton) said that they had a procrastinating politician as Minister of Health; they did not want to have a procrastinating chairman of any of their committees. He felt that they must have resignation in their minds and the Council must know that they were going to demand it.

Dr. J. A. Ireland (Council) said that he was rather perturbed about this resolution. He thought that the Kingston resolution covered all that was necessary at the moment, and he did not like to use the word "resignation." He moved therefore that the meeting proceed to the next business.

It was agreed to proceed to the next business.

The First Year of the Service

Dr. R. Hale-White (Marylebone) moved:

That this meeting of representatives from all parts of the country regretfully records the fact that during the first year of the National Health Service the Minister and the Ministry of Health have shown little or no desire for co-operation with the medical profession in its efforts to serve the public, that they have met the profession's suggestions with indifference and procrastination, that they have been guilty of breach of faith, and that these are added reasons why the Service is falling far below the standard the public were led to expect.

He said that they had talked already about various breaches of faith. They had heard from the Chairman of Council a strong expression of resentment at the procrastination of the Minister. It was hard for doctors to give of their best when they received this sort of treatment and were constantly anxious about their incomes. So far as private practice was concerned, the Minister had made no attempt to carry out promises given when the Act was brought in. The Minister and the Ministry were both mentioned in this motion for the reason that it was very difficult sometimes to know which was blameworthy. But it was the Minister who was bubbling over with talk about co-operation in the letter of July 3, published in the *British Medical Journal* last year. The profession had loyally done its bit, but what real evidence was there of co-operation on the part of the Minister?

Mr. A. Lawrence Abel (Marylebone), in supporting the motion, said that in the terms for the specialist service the word "specialist" was now omitted. The public who were promised specialists by the Spens Report were now to have consultants and senior hospital medical officers. There had been procrastination and breach of faith. This motion could be carried with a clear conscience and it would strengthen the hands of the Council.

The Chairman of Council said that he must adopt the unusual role of taking the Minister's part. At no time that he remembered had the Minister ever undertaken to support private practice. He had never had the slightest interest in private practice except to destroy it.

Dr. Hale-White explained that he had realized all the way that the Minister was out to destroy private practice. But before the Act came in he did say that anyone was entirely to do as much or as little private practice as he wished.

The Marylebone motion was carried with two dissentients.

Lay Control of Medicine

Dr. F. Lishman (Bishop Auckland) moved: "That this meeting views with great alarm the threatened lay control of medicine and recommends that appropriate action be taken. He complained of a circular sent by the Ministry which had been taken by many hospital secretaries as meaning that they were in control of the medical administration of the hospitals. He also complained of the remuneration of medical superintendents. Where the superintendents had administrative duties only it was proposed they should be paid on the same basis as the lay administrators; when they performed specialist duties as well they should be paid in proportion to the time they spent on such duties. Further in a recent issue of the *Municipal Journal* it was suggested that the medical officer of health of the future, like the medical superintendent, would not be a doctor but a lay administrator with a social science degree.

Dr. R. Kelson Ford (Chelsea and Fulham) said that practical work for the sick was in the process of being dragooned into subservience to bureaucratic domination. In one hospital the patients occupying paying beds had been told by the lay authority they need not pay a fee to the specialists. In another hospital a notice was put up that the operating theatre might be used only at certain hours. In another, a certain specialist turned up to take his usual out-patient clinic and found the room occupied by clerks and was told he was dispossessed. There was no other provision made for him until he was about to "pack up." In another hospital group the lay secretary of the management committee ignored advice from the medical advisory committee and proceeded to write letters to the Regional Committee in a contrary vein without informing the medical advisory committee that he had done so. As for general practitioners, certain of them had been told that they must hold more surgeries, and indeed must hold two at the same time in different places. This was an indication of the way things were going under the direction of bureaucratic control.

Dr. S. J. Firth (Brighton) supported the motion. This type of control, he said, was typical Civil Service, and all the regulations which were framed by the lay administrative people could lead only to frustration. Doctors in the Service in hospitals were already feeling the effect of this new machine.

Dr. James Fenton (Council) supported the motion. He had seen examples of junior clerks in public health departments who prior to last July were engaged in environmental work and who had now been sent to the hospital service, taking charge over medical superintendents.

Dr. Doris Odlum (Bournemouth) said there was no doubt that both doctors and patients were being sacrificed to political expediency and to the Civil Service mentality, and it was a great tragedy that it appeared that the Minister was hardening on this point of lay experience in medical administration. In the original draft from the Ministry on terms and conditions for consultants and specialists it was said that half the time of the administrator should be paid at the administrative rate, and that he should get his clinical pay only for the period he was actually giving to clinical work. Some slight qualification was made in the case of long-stay hospitals, but was afterwards withdrawn. The work of medical superintendents in mental hospitals and other institutions, which was what might be called medical administration, was greatly in the interests of patients, who would suffer severely if medical men and women were discouraged from entering for these posts. It would be most unfortunate if the work should fall into the hands of lay administrators.

Dr. A. Beauchamp (Birmingham) said that he was in full agreement with the case made out, but he did not think the meeting should support the resolution as it stood. He was not himself aware of any threatened lay control in general medical services, and it should be made plain that it was hospital services which were in view.

Dr. P. Phillips (Bristol) spoke of the unfortunate position in which deputy superintendents, men who had done perhaps ten years' service and were aspiring to superintendent posts, were placed. Those of them who were consultants or "consultoids" might not have a great deal to complain of, but he was glad to support this motion.

Dr. W. N. Leak (Mid-Cheshire) said that if this went on it would mean, not a medical service, but a service controlled by non-medical people. Dr. A. Smith (Lanarkshire) said that the medical administrator was essential in every hospital. And what was going to happen to the general practitioner, if this kind of thing went on, when they set up health centres? Miss Gladys M. Sandes (Marylebone) said that some social workers were apparently to be given the discretion as to whether an aged person should really be admitted to hospital or not. Mr. C. F. Mayne (Plymouth) said that lay administration in committees was essential, but political lay administration, which was often to be found, was not essential.

The motion viewing with great alarm the threatened lay control of medicine, and recommending appropriate action, was carried unanimously.

GENERAL MEDICAL SERVICES

Dr. S. Wand (Chairman of the General Medical Services Committee), in bringing forward the Report of Council under that heading, gave an account of the work of the committee. The case on which the Special Representative Meeting agreed had not yet been discussed with the Ministry. Both the officials of the Ministry and the Minister himself had made it quite clear that they did not propose to give an answer on the case until the results of the inquiry had been analysed. But at the first interview two important issues arose. They were told that any modification of the pool would not necessarily be retrospective to July 5. The other matter related to the attitude on arbitration which had been discussed that morning. It was made clear they had no right to automatic arbitration, though arbitration was not ruled out. The results of the inquiry were expected to be published next month. It was quite clear that in computing the size of the pool, and the amount of money that went into it, the Ministry would put in every single penny that was earned by general practitioners in the Service. The application that the profession had made for a greater sum of money had been spoken of in some quarters as if it was an increase; it was not an increase, it was merely a proper assessment of the remuneration due to general practitioners since the appointed day. In the meantime this delay in settlement was causing considerable dissatisfaction among general practitioners. They were anxious to see this Service develop in the best possible way, and they hoped that by automatic arbitration all these unpleasant and unnecessary bickerings over money would cease. The public had a right to demand that the general practitioner should be free from these anxieties. The view was quite rightly held that the general practitioner had had a raw deal. He thought that statement was borne out by the report of the Select Committee. Having regard to the burden he carried, the general practitioner, relative to other professional groups in the Service, had been down-graded, not merely financially but clinically as well. ("Hear, hear.")

Dr. Wand then proceeded to give a brief review of the work of the General Medical Services Committee since it was created last November. He read a long list of its achievements and of the matters which had come under its consideration. These included the evidence to the Legal Committee on the partnership problem; the work which resulted in the enlargement of the mileage fund; the remuneration of general practitioners for services rendered in convalescent homes; the question of fees for locumtenents while practitioners were taking refresher courses; matters relating to the Pensions Scheme, devised to fill in the gaps in the Superannuation Scheme; the training of assistants; the position of the general-practitioner specialist; the statistical inquiry into the work of doctors; the temporary resident problem; the inflation of doctors' lists; rural practitioners' problems, and very many other aspects of the Service. With regard to inflation of doctors' lists, it had been impressed upon the Ministry that it would be advisable to reconstitute a Central Register such as existed in the old days; they had secured a promise that all possible steps would be taken to reduce inflation, and if those steps were not adequate the possibility of a Central Register when the census was taken in 1951 would be considered. Another matter which had engaged the attention of the committee concerned the reintroduction of rules of conduct for patients, including the setting up of some disciplinary machinery. A subcommittee had been set up to consider the problems affecting general practitioners who would go into health centres. In regard to some of these questions the committee had got what it wanted; in regard to others it was making progress.

Dr. Wand concluded with a tribute to the late Dr. John Bone and his great work for the old Insurance Acts Committee and the Defence Trust. His would be a name they would always remember with great affection. He also referred to the magnificent work done by the present chairman of the Representative Body, Dr. Gregg, as chairman of the Insurance Acts Committee.

Constitution of Committee

Dr. Wand went on to move approval of the paragraph in the Annual Report (25) setting out the proposals for the constitution of the General Medical Services Committee.

Dr. D. L. S. Johnston (Halifax) had down an amendment to the effect that the committee should be reconstituted to form the executive body for all general practitioners grouped within the framework of the Association in areas conforming to the present Divisions; that representatives on this executive body should be elected directly by vote of practitioners, each constituency conforming to a Branch Council area, the Central Conference also electing representatives; that the executive body should be subject to no other body by veto in matters which had been decided by a central conference composed of representatives of the practitioner group; and that the executive body should have direct access to the Minister of Health. He said that this was put forward in no spirit of criticism, but only to ensure that the periphery would be well informed as to the action of the centre in any eventuality, and that the periphery would get rid of its apathy. Since he had tabled this motion, however, a good deal of water had run under the bridges, and in particular there had been set up the British Medical Guild. Therefore he proposed, with the leave of the meeting, to withdraw the motion.

Call for Withdrawal from the Service

Dr. H. J. Cronhelm (Belfast) moved:

That owing to the unsatisfactory situation which has arisen due o the indefinite postponement of discussion by the Ministry of Health of the reasonable and documented case put forward by the General Medical Services Committee for increasing the Central Pool by £16,500,000, this meeting demands that further delay shall not be tolerated, and that the Association take immediate steps to organize a mass withdrawal from the Service.

He said that the Minister had shown no desire to treat their claim as the urgent matter which it certainly was. He had adopted a technique of delay and obstruction. There was one course open to them, to have nothing further to do with the Health Service. The latest promise from the Minister was that his inquiry would be completed by July, but it might well go on to August and September. The machinery which was an essential preliminary to any concerted action by the profession should now be set in motion.

Mr. Eric Steeler (Marylebone) said that the motion reminded him of the definition of a love-letter—the writer should start by not knowing what he was going to say and end by not caring what he had said. If they withdrew *en masse* it was the British Medical Guild to which they must pin their faith, and he had already sufficiently criticized that organization.

Dr. R. V. Goodliffe (Croydon) complained that all the resolutions at the present meeting which called for action had been whittled down or put out of the way. Dr. Dain had said that if they did not get satisfaction they might at some time in the future have to consider withdrawal from the Service.

Dr. Dain: I spoke more definitely than that.

Dr. Goodliffe asked what had happened since that speech was made earlier in the morning. The meeting, which was alert and keenly receptive to that suggestion, had gone on to permit the withdrawal or whittling down of any resolution which called for action. This was the last opportunity they would have of putting into actual effect the enthusiasm they showed when Dr. Dain addressed them.

Dr. H. Alexander (Wandsworth) said that the National Health Service was about to celebrate its first birthday. It was born prematurely; in fact there was difference of opinion as to whether it was a viable child. It owed its survival to the devotion of the doctors. One might have expected that its political father, so proud of his child, imperfectly developed as it was, would have shown some kind of appreciation of the doctors, but in fact he had rewarded them with scant respect. He had gone forward without consulting the profession and he still refused to pay the "confinement fees." (Laughter.) It would always be true that doctors were loath to take legal action, but the time had come when at least a strongly worded "solicitor's letter" should be written pointing out the inevitable consequences of refusal on the part of the Minister to meet his obligations.

Dr. F. A. Roper (Cornwall) said if this was passed it would be a mandate to the Council to organize mass withdrawal forthwith. He noticed, however, that the proposer had taken another line, for he had interpreted the word "organize" as meaning "asking the Council to explore the possibilities." He suggested this resolution required amendment to make it clearer in the light of the mover's speech.

Dr. D. S. Saklatvala (West Bromwich and Smethwick) moved as an amendment that the termination of the Belfast motion should read: " . . . take immediate steps to enable a mass withdrawal to be effected at any time."

Dr. C. R. Barrington (Bromley) agreed with the amendment. If the machinery was in being it would make any action they took very much more effective. Dr. A. G. Holman (East Norfolk) said the word "resignation" was often used, but could they be sure that they had the Divisions behind them? Divisional meetings were often poorly attended. He had been told that in certain industrial areas doctors feared physical violence if they refused to treat their patients under the National Health Service. Dr. H. Barbara Woodhouse (Harrow) said that it was for representatives to organize in their localities and educate their fellow practitioners on this vital issue. The last speaker had suggested that if doctors resigned they might suffer. If they were not prepared to face sacrifices she did not think they were worthy to be called supporters of the cause of freedom. (Applause.) Dr. W. R. E. Harrison (Brighton) said that if the rank and file got the idea that the B.M.A. stood for peace at any price, then they had "had it."

The amendment proposed by Dr. Saklatvala was agreed to. In further discussion on the substantive motion Dr. G. O. Barber (Mid-Essex) said that the motion was a weakening of their previous motion insisting on arbitration. This subject should be left to arbitration, and if arbitration were not granted they should proceed with withdrawal. Dr. J. C. Wishart (Bromley) said that if they went back to their constituencies and said that preparations were being made to organize this withdrawal it would be the best means of combating Divisional apathy.

Dr. T. W. Morgan (Kingston-on-Thames) reminded the meeting that that morning it had passed unanimously a motion on arbitration which meant that they did not allow the Minister a veto against the profession. But the Belfast motion meant that they were holding a veto against the Minister.

Dr. Wand hoped that the amended motion would be passed. He thought it met what the Representative Body would wish done at this moment.

The motion in the following form was carried with one or two dissentients.

That, owing to the unsatisfactory situation which has arisen, due to the indefinite postponement of discussion by the Ministry of Health of the reasonable and documented case put forward by the General Medical Services Committee for increasing the pool by £16,500,000, this meeting demands that further delay shall not be tolerated, and that the Association take immediate steps to enable a mass withdrawal to be effected at any time.

A motion by Dr. T. W. Morgan (Kingston-on-Thames) demanding that the contemplated improvements in remuneration should have effect retrospective to the commencement of the Service, seeing that the present capitation fee had never been agreed by the profession, was carried.

Dr. G. R. Mitchell (Blackpool and Fylde) called for full support for the Conference of Local Medical Committees in seeking adjustment of general practitioner remuneration on the basis of the report prepared by the General Medical Service Committee, and stressed the urgency of the matter in view of financial hardship. Until last July in his area private practice largely predominated over insurance practice. Among many practitioners who formerly had good private practices financial hardship was acute.

A motion to this effect was agreed to.

Mr. J. Shirley Callcutt (Wembley) moved: That this meeting considers that the amount of the capitation fee is not equitable throughout the country and should be made uniform irrespective of area and of other payments such as mileage and dispensing. The figures for mileage, dispensing, etc., should be separated from the global sum, and division made among general practitioners according to the number on each list.

Dr. Wand reminded the meeting that the pool method was the only way in which the capitation fee for 95% of the population could be got into the pockets of the doctors.

The motion was lost.

Temporary Residents

Dr. C. J. B. Fox (Consett and Hexham) said that the fee of 15s. for attending temporary residents was totally inadequate. As it specially affected seaside and holiday resorts, where the patients called in medical aid only in the event of severe disability, his Division considered that the fee should be not less than one guinea.

Dr. E. G. Smallbone (South Essex) said that this was a matter which should be decided by actuarial investigation, not by a show of hands at that meeting. Dr. S. Noy Scott (Plymouth) said that thousands of cases were sent for convalescence and required no other aid whatsoever, beyond a monthly certificate. They must not lose their sense of proportion. Dr. E. W. Vincent (Scarborough) pointed out that a town might have a population of 5,000 in winter and 20,000 in summer, and by any computation a large number of these additional people must require medical attention. A large

number of the people who fell ill at seaside resorts were children, who required a great deal of attention.

After further debate, during which more than one representative produced figures comparing holiday resorts with industrial areas in respect of the number of temporary residents, Dr. Wand said that when this matter was discussed the representatives from holiday areas were invited to attend, and the figure of 15s. was agreed by them to represent a fair remuneration. The moment they started to go above a fair remuneration they were taking money unnecessarily out of the pockets of other practitioners. In a year's time let this matter be looked into again. It might be that this 15s. would prove inadequate and then it would have to be revised.

On this understanding Hexham withdrew its motion.

Mileage Payments

Dr. H. B. Muir (Fife) asked the meeting to express the opinion that payment for mileage under the maternity scheme should not be deducted from the central mileage fund. In a long speech fortified with many figures from his own practice he said that there were many reasons why the two types of payment should be divorced. He complained that Dr. Wand did not understand the mileage question in connexion with rural practice, and especially the question of maternity mileage.

Dr. D. M. Hughes (South-West Wales) said that since the last Representative Meeting he had come to see that the position in rural areas in respect of mileage was much better than he had thought. He was afraid they might have trouble if they flogged this mileage question in the future.

After Dr. J. O. McDonagh (Perth) and others had spoken, Dr. Wand said that he thought they had done rather well for rural practitioners interested in mileage, having attached to them a sum of half a million new money. He reminded the meeting that they had agreed to a pool method of payment. All moneys paid to doctors came out of the pool. If extra money were taken for a particular section of the work it came out of the pool, and thereby other items in that pool were lessened in a financial respect. As they had attached themselves to the pool system, his committee had referred to the Rural Practitioners Subcommittee—to whom else could they go?—and received its endorsement. He hoped that until they got the global sum question settled there would be no more talk of little bits here and there being taken out of the pool. "Do not let us make major political issues out of what are isolated cases of maladjustment."

The Fife motion was lost.

The session concluded at 6.15 p.m.

SATURDAY, JUNE 25

The meeting began at 9.30 a.m., with Dr. Gregg in the chair, and further motions arising out of the section of the Annual Report dealing with General Medical Services were taken, starting again with some discussion of the payments for mileage.

Dr. A. H. Forman (Fife) asked the meeting to express the opinion that payment for mileage under the maternity scheme should be on a similar basis to that prevailing under the Maternity Services (Scotland) Act, 1937—namely, a compromise payment for each case booked or a payment for each mile travelled over two miles from the patient's residence for each visit to the patient's home, special visits being paid at the full rate and visits in the course of a round at one-third of the full rate, the choice of method being left to the doctor. He did not see why practitioners should not receive mileage in respect of this service as they had for the past few years. The fact that it was not received in England was beside the point. His Division was not asking for something to which they were not entitled; they were entitled to ask for every penny of mileage they could get. Patients in towns would attend clinics, but in the country they would not; bus services were not always convenient, and in any case it was unfair to ask an expectant mother in the last six weeks of pregnancy to travel in some of the rural buses. He asked for support of the motion to help rural practitioners to obtain this extra money.

Dr. W. Jope (Council) said that the meeting should not be asked to waste its time discussing details of payment, and this matter should be referred to the Remuneration Subcommittee of the General Medical Services Committee.

Dr. S. Wand said that there still seemed to be an idea that this money was coming from some separate fund which bore no relation to the pool. This was not the case: the mileage money was a first charge on the Mileage Fund. The Rural Practitioners Committee in their wisdom had made an allocation from that fund for maternity mileage. The rural mother had to be examined antenatally quite frequently at her home, and allowance had been made for this; allowance had further been made for the fact that in many cases the mother was on the list of the doctor, and mileage was given for that purpose also. Allowance had been made for the fact that in some cases the mother would move further away from her home for the confinement; in others she would go nearer to the place in which the doctor was practising. Thus it would be seen that the problem had been discussed in all its aspects, and he would ask the meeting to accept this motion as a reference to the Committee, bearing in mind that the arrangement had only recently been made and should be allowed to run for some time to see whether it needed revision.

Dr. Forman, in reply, agreed that the matter should be passed to the Council for consideration, but he took exception to Dr. Jope's remark. Representatives were sent by Branches to express their points of view, and if they were not allowed to do so it was a waste of time to attend.

The motion was withdrawn on the understanding that the matter should be referred to Council.

Treatment of Miscarriages

Dr. J. M. Gill (Aberdeen and Kincardine Counties, Orkney, and Shetland) asked that the treatment of miscarriages should be regarded as outside the ordinary terms of service of a general practitioner, and paid for on the same basis as a confinement, irrespective of whether the woman had signed E.C.24 or not. He said that though part of the resolution had been conceded (on which he congratulated the B.M.A.) it did not go far enough. His Division felt that a miscarriage should qualify for a Part I payment. An emergency confinement qualified for 4½ guineas, and the only justification for the difference would be if a miscarriage did not require the same knowledge, judgment, and skill as an ordinary confinement. This was nonsense. The conduct of a miscarriage at any stage might call for as much skill and judgment as a confinement, and might occupy the doctor for as long. His Division also felt that it was as necessary for a post-natal examination to be carried out six weeks after a miscarriage as after a confinement. The payment for miscarriages should be the same as for an emergency confinement, and if the miscarriage had taken place between the 25th and 27th week and any antenatal visit had been made that also should be paid for.

Dr. S. Wand said this was what was called "wanting jam." As general practitioners they knew that in the nature of things it was most unusual for a miscarriage to require anything like the same amount of attention. He would not go into details, but he hoped it would be agreed that the arrangements made with the Ministry were satisfactory.

Dr. Gill felt that Dr. Wand must have been luckier in some of his miscarriage cases than practitioners in the country, where they had to deal sometimes with very serious emergencies. If they were entitled to a post-natal fee for a confinement (and a post-natal examination was necessary after a miscarriage) his Division felt that they should be paid the fee for that also.

The motion was lost.

Basic Salaries

Dr. J. W. McCarthy (Hendon) moved to instruct the Council to represent to the Ministry that all basic salaries granted by Executive Councils should be a primary charge on the central pool. He said that since the poster sent out by the Association had been displayed in consulting-rooms patients had realized the small part of the contribution which went to the doctor.

Even the more enlightened had thought the doctor received the whole 18s. capitation fee, but this was not the case. Last year in Middlesex practitioners received 15s. 7d. capitation fee for the whole year. Different reasons for this disparity were given : (1) inflation of lists, (2) inaccuracy of the registration figures, and (3) the number of basic salaries. These last were controlled by the Local Medical Committee ; if a man was refused a basic salary he appealed and it was taken out of the hands of the local committee ; there was a case, he submitted, for basic salaries to be paid out of a central pool.

Dr. H. F. Moffit (North Glamorgan and Brecknock), speaking as an industrial area representative, asked the meeting to reject the motion. He agreed that there should be special payments to "truly rural practitioners," but if Dr. Wand's campaign for an extra £16m. to be put into the central pool and an increased capitation fee for the first thousand patients was successful discrepancies would disappear in respect of scattered rural areas. If this motion was accepted they would be one step nearer a full-time salaried service ; it would lead to a greater number of practitioners seeking and getting the basic salary, which would mean a large drainage on the central pool and consequent reduced capitation fees all round. There must still remain the rate for the job, and doctors with small lists in residential suburbs should not expect basic salaries to be paid out of the central pool and thus reduce the capitation fee in all other areas. Practitioners in industrial areas did the work in the past ; they were doing the work to-day, and were strongly opposed to this proposal.

Dr. R. W. Cockshut (Hendon) said that in Middlesex there were very densely populated industrial areas. His Division was asking for a simple act of justice. Basic salaries existed and he did not see why they should not come out of a central pool. Middlesex was a distressed area in that it had a higher proportion of doctors to the population than anywhere else in the country ; they had been hard hit, which meant that an abnormal number of basic salaries had to be paid. If the housing situation was easier many would have moved into areas where the proportion of doctors to the population was not so high, and if that had happened such areas would have felt the difference. The strictest supervision should be exercised on the payment of basic salaries, and to make them a first charge on the pool was an act of justice which could not be refused.

Dr. H. B. Muir (Fife) supported the motion because anomalies did exist. In one area in Scotland 18 out of 20 doctors were entitled to basic salaries—a quite impossible situation.

Dr. S. Wand said he would ask the Representative Meeting to bear in mind not only the immediate problem but the major issue involved. The greatest fear with regard to the Service was the possibility of a universal basic salary which might be steadily increased until it became the major part of a practitioner's income, with a resulting drift into a full-time salaried service. In the area quoted by the last speaker a case could be made out for a larger number of payments from the Special Inducement Fund, and more of these applications should be made. In the case of Middlesex he agreed that there had been some anxiety, but the matter had been taken up and an endeavour was being made to put it right. Because there was this immediate difficulty in Middlesex, however, they must not do something which would create a major issue at some future date.

Dr. McCarthy, in reply, said that Hendon had worked as hard as any area in the fight. He thanked Dr. Wand for his interest in Middlesex, but his constituents were looking for results. The payment for the last quarter was lower than ever. Basic salaries paid from the central pool would be better controlled, and every doctor would get a fairly equal return for the work he put in.

Dr. Wand, in reply to a question whether if the increase on the first thousand patients were obtained the Committee would explore the possibility of abolishing the basic salary, said that the Representative Meeting was told that it was hoped that the extra payment would result in the abolition of the basic salary. The Committee would have that in the forefront of its mind.

The motion was lost.

Dr. G. MacFeat (Council) called upon the meeting to take grave exception to the action of the Secretary of State for Scotland in granting, on appeal, certain fixed annual payments previously refused by both local medical committees and executive councils. He said that his Division was seriously disturbed at the action of the Secretary of State in granting appeals of practitioners who were refused basic salaries by the local medical committees and the Executive Council. It concerned practitioners with sufficient lists to produce an income of £900, practitioners refused for unethical conduct, and two glaring cases of practitioners who had been practising for some years and had in no sense developed practices. He desired to protest in the strongest terms against this action. The assessment of need for basic salary was one of the most unpleasant duties imposed upon medical committees and executive councils, and to have their work overturned without rhyme or reason was most unjust.

Dr. D. F. Hutchinson (West Middlesex) moved, as an amendment, that "the Minister of Health" be inserted in the motion before "the Secretary of State for Scotland." The meeting would do well to support this motion. In one case where the basic salary was refused it went to the Minister on appeal ; the appeal was refused, but the practitioner's solicitor wrote what he described as a grossly improper letter to the Minister, as a result of which the Minister decided to reconsider his decision. The result was not yet known, but the Executive Council had taken strong exception to it. He agreed that the appeal should not lie with the Minister but with some other body, and he felt it should be the Medical Practice Committee.

Dr. A. V. Russell (South Staffordshire) seconded the amendment and supported the motion. Dr. F. M. Rose (Preston) said, in supporting the amendment and the motion, that Lancashire had had to deal with many applications and had been strict in its consideration of these claims, but the Minister had granted appeals which no medically constituted committee would have granted.

Dr. F. Gray (Council) said that the Minister had managed to do a quite extraordinary thing ; he had managed to convince the lay members of the London Executive Council of the dishonesty of his department. In London every case had received serious and careful consideration, and appeals had been allowed where they should not have been allowed. When the Minister deliberately perverted the course of justice it was time that these appeals were taken right out of his hands and placed in the hands of those who could be trusted to see that justice was done.

Dr. MacFeat accepted the amendment. He said that this was a very serious matter ; the local medical committees and executive councils had a sense of frustration when their decisions were turned down without proper inquiry, and this was not helpful in the development of a satisfactory medical service.

The motion as amended was carried unanimously.

Vaccination and Immunization

Dr. Wand moved approval of the paragraph in the Annual Report dealing with vaccination and immunization. There had been during the last week or two a change in the position which made them feel that they could once again go into conference with the local authorities and the Ministry, and they were awaiting a date for that meeting. The general approach was now established and bade fair to be rather more satisfactory.

Dr. E. C. Dawson (Derby) moved as an amendment that the fee for vaccination should be one guinea and for immunization 5s. for each injection. In vaccination, he said, there were normally three attendances. If each of these was to be counted for an attendance fee, £1 2s. 6d. could be claimed. But difficulties sometimes arose and examination might have to be made every day, which would bring about a heavy bill on the basis of daily attendance. It was thought by his Division that the best way out of the difficulty would be one inclusive fee of a guinea.

Dr. James Fenton (Council) asked that the reference to immunization might be omitted. Immunization was in his view not treatment but prevention, and a separate fee should be paid by the local health authority. He was satisfied that it

would embarrass Dr. Wand if they fixed a 5s. fee for immunization for each injection.

Dr. S. Noy Scott (Plymouth) reminded the meeting that there was such a thing as "killing the goose." To ask for a fee of one guinea for a vaccination was suggestive of that. It was a very simple operation which took up a very short time, and what was asked for in the Derby amendment seemed out of all proportion.

Dr. Wand protested against motions which tied the hands of the committee in this way. Dr. Dawson, in reply, said that if they accepted the recommendation as laid down in the Council's report of 7s. 6d. for attendance, and there were at least three attendances at each vaccination. (Voices: No, two.) He understood they should look for an accelerated reaction on the second or third day and for a normal reaction on the seventh day, and in that case the payment would be £1 2s. 6d.

The Derby amendment was lost.

Dr. W. Smith (Greenwich and Deptford) moved to ask the meeting to regard the Minister's continued refusal to agree to payments of fees for vaccination and immunization as indefensible. It seemed that now the clinics would be able to do all these services; that was supposed to be progress. Did they wish that immunization and vaccination should be carried out to the greatest possible extent? If so, the Minister was not helping the public to obtain what they should.

Dr. Wand considered that this was a matter for local authorities. The trouble was more local authority than ministerial.

It was agreed to pass to the next business.

Dr. J. C. Arthur (Gateshead) moved:

That until it be established that local authorities are responsible for the payment to practitioners of fees for the performance of vaccinations and immunizations, it is recommended that no reports of the performance of such services be rendered.

He said that the service could not be refused, but there were other directions in which the profession could take effective action, and the withholding of reports was one of them.

Dr. A. G. Holman (East Norfolk) said that the Ministry and the local authorities were indulging in a game of "passing the buck." In his area they had adopted the plan of performing the service but holding on to the record until the question of responsibility for payment of fees had been determined.

Dr. Wand said that it would be indefensible, while negotiations were in progress, for an important body to pass such a motion as its official policy.

Here also the meeting decided to proceed to the next business.

Dr. J. W. McCarthy (Hendon) asked the meeting to express the definite opinion that immunization and vaccination should fall outside the scope of the contract for public practitioners, and be made the subject of separate remuneration, both for the services and for the reports involved.

Dr. Wand again deprecated such a resolution at the present moment while negotiations were pending.

The meeting again resolved to pass to the next business.

Special Facilities in Hospitals

Dr. J. S. Ross (East Herts) moved that the maintenance of pathological and radiological facilities for general practitioners without the intervention of a consultant in a hospital out-patient department was essential. He said it seemed as if there was a further attempt here to exclude general practitioners from the hospital service. They were apparently considered incapable of deciding when *x*-ray examination was needed.

The general practitioner was prepared to co-operate in reducing the demand on *x*-ray departments and in discouraging patients from making unreasonable demands, but he hoped that this matter of facilities would be taken up very actively with the Ministry so that general practitioners might have these facilities for diagnosis maintained.

Dr. T. F. Tierney (Marylebone) said that he was a radiologist both to a teaching and to a country hospital. In the country hospital any practitioner could send a patient without interference, merely because they had facilities and the time to carry out the amount of work which was needed. In the teaching hospital there was so much work going through the department that it was a physical impossibility for the department to cope with more than that sent to it by the hospital, and this filtration through the out-patient department was the method they had adopted for their own protection.

Dr. Ff. Roberts (Cambridge and Huntingdon) said he was entirely in sympathy with the general practitioner and could not see why any difficulty should be put in his way. What could be more calculated to down-grade general practitioner work than artificial barriers to such facilities in hospitals? When *x* rays were introduced 50 years ago it was the general practitioners who took up the method, and they had difficulty in persuading many consultants as to the value of this new "toy." The *x*-ray pioneers were general practitioners. If the patient went through the hospital departments the amount of work attaching to him was likely to be increased. A general practitioner would be satisfied to know whether the patient had had a gastric ulcer or not, but in the out-patient department the patient would possibly come into the hands of one of the junior registrars and time would not be saved, because he was likely to be referred for many investigations.

Dr. D. E. Yarrow (Tunbridge Wells) said this was a question of the general practitioner retaining some clinical interest.

Mr. H. H. Langston (Winchester) said some members appeared to think that consultants wished to prevent the general practitioner from having access to these special services. On the contrary, consultants felt that the general practitioner should be able to investigate his cases as fully as he thought necessary. But in his own hospital there was a three-weeks waiting-list for *x*-ray investigation of cases of gastric ulcer, and he could assure them that to open the departments to general practitioners at the moment, in view of the great amount of investigation work required, was impossible. Consultants were not out of sympathy with general practitioners in this matter.

Dr. J. M. Alston (City) proposed the addition of the following words to the motion: "and should be extended as facilities become available." As a pathologist he found that most of them were unable to carry out their good wishes towards the general practitioners because of shortage of space, staff, and materials.

Dr. W. Smith (Greenwich and Deptford) seconded the amendment. The motion without the amendment was impracticable. Much work in the pathological departments was now done by technicians without medical supervision, so that if the patients were sent to departments of that kind it would result merely in reports being obtained which were not necessarily completely informative.

Mr. R. L. Newell (Council) said he heartily agreed with the principle underlying the motion and the amendment. If they were to maintain the high standard of general practice it was essential that they should provide general practitioners with these facilities. It was perfectly true that the departments in the large hospitals had been overloaded. The overloading was due to many causes, one of them the fact that they appeared to be teaching their younger people that no diagnosis was possible without submitting the patient to innumerable pathological and *x*-ray investigations. Nevertheless, the absence of facilities should not deter the meeting from passing the amendment, which improved the motion.

Dr. T. W. Morgan (Kingston-on-Thames), as one who was intimately connected with two small but busy hospitals, had considerable sympathy with some of the remarks made by the consultants. On the other hand, there was a demand throughout the country to exclude general practitioners from staffs of cottage hospitals. Consequently, as a general practitioner he asked the meeting, in order to assist the departments while further arrangements were being made for this service, to be particularly discreet in their demands on the Service. But, for heaven's sake, let them keep the Service in their hands.

The motion was carried in the following form:

That the maintenance of pathological and radiological facilities for general practitioners without the intervention of a consultant in a hospital out-patient department is essential and should be extended as facilities become available.

Legal Advocacy in Medical Service Cases

Dr. R. Forbes (Hendon) moved that the Council be urged to make early representations to the Minister to amend the

regulations governing the procedure of medical services committees to bring them into line with those applicable to Northern Ireland, whereby a defendant doctor appearing before a medical services committee may have, if he desires, the services of a paid advocate or solicitor.

The practitioner should not be left alone without skilled assistance in the presentation of his defence. There was a growing volume of evidence that at the present time there was an increase in the number of cases finding their way to the medical services committees. This was perhaps due in some measure to the introduction of a new section of the community —a better-paid, perhaps a better-educated, section—at all events a section more conscious of its rights. These people were now making more frequently a complaint against doctors on the grounds of negligence or impropriety of conduct of one sort or another. Not uncommonly they used such action as a forcing point to see what success might follow a complaint of that kind. If they gained a favourable decision at the medical services committee they might possibly go on to the Courts of Law or to the General Medical Council as complainants against the doctor. Many doctors were quite unable effectively to present a good defence on their own behalf, even though a good defence was possible. Many did themselves more harm than good by attempting to present the case on their own behalf. In this changed set of circumstances the defence societies in their experience thought that the time had now arrived when the profession should ask for the right to have representation of a medical practitioner by a paid solicitor or advocate if the practitioner so desired.

It was recognized if that right was given to the doctor it must also be given to the other side. But it was believed that the exercise of that right on behalf of the doctors would protect them in a way in which they could not be protected at present. He hoped he could enlist their sympathy in providing for the defendant doctors who had to appear before these committees on a serious charge the right to be legally represented and to have put forward on their behalf as good a defence as was possible in the circumstances of the case.

Dr. Frank Gray (Council) said there was a good deal of substance in what Dr. Forbes had put forward, but he asked the meeting to look carefully on the other side of the question. If the doctor had paid skilled assistance the other side would have it also, and, whilst undoubtedly skilled assistance would be a great help to the doctor, to have a skilled lawyer on the other side cross-examining him might possibly produce results which in the long run would be of no benefit to the doctor. He added that every secretary of a local medical committee had a statutory right to be present at such hearings.

Dr. E. C. Dawson (Derby) thought they must be very careful on this question of paid defence, which might well prove to be a double-edged weapon.

Dr. D. S. Saklatvala (West Bromwich and Smethwick) spoke in support of the motion. He said sometimes political bias operated among members of the committee. If they were faced with such bias the frequency of appeals would increase, and it was clearly to the advantage of the doctor to have properly trained advocacy at the earliest possible stage.

Mr. G. Whyte Watson (Bradford) said that strict justice was better than rough justice. They could not get strict justice in its entirety, but when there were legal arguments they approached nearer to strict justice. He begged that the doctor might have this help if he so desired.

Dr. E. J. Warburton (Reading) opposed the motion. To have the doctor himself present with a colleague was by far the best possible arrangement. All the doctor needed to do was to be honest, fair, and straight, and he had medical colleagues on the committee.

Dr. E. J. Allan (Buxton and Glossop) described the method adopted in Derbyshire whereby the doctor got all the advice he needed without the necessity for paid legal advocacy. He thought the meeting should be careful before passing a motion of this kind.

Dr. F. M. Rose (Preston) said that from his experience the present set-up did not work to the disadvantage of the general practitioner. Recently in a medical service case a doctor did bring a solicitor friend with him. He was admitted as a friend and he put a number of questions to the complainant, but this did not help the doctor in this particular case and the finding went against him.

Dr. Wand said that his committee had considered this matter very carefully indeed, and the experience of those who had served on the old medical services committees under N.H.I. was such that they felt it would not be an advantage to allow lawyers to enter into the matter at this stage. In some respects they were not altogether happy about the whole of this disciplinary machinery and they were proposing to have a look at it again next year in the light of experience.

Dr. Forbes, in reply, said that he was still unrepentant. Before this resolution was formulated discussions had taken place in the councils of the defence bodies themselves and agreement had been reached upon the desirability of having the regulations changed. The defence bodies saw this problem with all its difficulties. They found they had to consider cases of negligence which would never have come to light at all if it had not been that the complainants learnt the facts owing to the irregular procedure of these committees.

The motion by Hendon calling for the right to a defendant doctor to have the services of a paid advocate or solicitor was put to the meeting and carried by a very small majority. The voting was:

In favour	125
Against	123

A recount was demanded, with the following result:

In favour	127
Against	126

Demands were made for a further recount, for a roll call, and for a card vote, but on a motion from the meeting the Chairman decided to proceed to the next business.

At this point it was agreed that in view of the state of the agenda the time limit on speeches should be reduced from 10 minutes to 5 minutes for proposers of motions and to 5 minutes for other speakers.

Treatment of Dental Haemorrhages

Dr. D. S. Robertson (City of Edinburgh) took strong exception to paragraph 49 of the Annual Report of Council, which stated that the Minister had been informed that, in view of the position with regard to the ruling of the Minister concerning the treatment of cases of dental haemorrhage, unless the decision was modified general practitioners would be advised to refuse to accept service in cases of haemorrhage arising from dental operations. Dr. Robertson said that this paragraph advocated withholding of service from people who might be in dire need, and therefore it abrogated the principle the Association had always supported. He submitted that this was a denial of their sacred duty as doctors, and he refused to follow this advice of Council. He had known one case of death following dental haemorrhage. Suppose that happened, how could they ever justify themselves before any tribunal, least of all the tribunal of their own consciences? This was a form of strike, as blameworthy as that of strikes which impeded the food supply of the nation. Edinburgh proposed that treatment should not be refused in cases of dental haemorrhage, but that pressure should be continued to obtain a fee for such emergency service. He would be very disillusioned and saddened if one voice was raised against the Edinburgh amendment.

Dr. G. de Swiet (Paddington) agreed that they should not refuse treatment in these haemorrhages but should press for a better payment such as they got for dental anaesthetics.

Dr. H. W. Pooler (Chesterfield), who described himself as the oldest practitioner present, not only in years but in period of service, said that he had been much worried by these cases of dental haemorrhage. He had never refused to do his best for the patient and he would never contemplate any such refusal.

Dr. Wand said that his committee had quite recently reopened discussions with the Ministry on this point and was not unhopeful of obtaining a reasonable settlement.

He suggested the meeting should pass to the next business.

The meeting, however, demanded to vote on the Edinburgh amendment, which was carried by an overwhelming majority.

Dr. J. C. Arthur (Gateshead) moved:

That in the event of his being called upon to deal with a dental haemorrhage a medical practitioner should be able, as a dentist is able, to claim suitable payment from the Dental Estimates Board.

He said that this matter had for a very long time been a continuing source of anxiety in the minds of practitioners. The primary responsibility for dealing with a dental haemorrhage was with the dentist.

The Gateshead motion was carried.

Frivolous or Unjustified Calls

Dr. A. Maiden (Lincoln) asked that steps be taken to persuade the Minister to set up a series of rules for patients comparable to those used under the National Health Insurance Act.

He said that what was put forward in the Lincoln motion was now more or less Council's policy. Prior to July 5, under the old N.H.I., there were several ways in which the patient could be penalized. For flagrant violation of the doctor's time and patience the patient could be fined up to a statutory maximum amount, increased for a second offence, and he could have his medical benefit withdrawn for a definite period, though this was seldom done. In his experience in Lincolnshire 98% of patients were courteous and considerate and in no way could be accused of being awkward, but the other 2% were apt to be beyond endurance. The doctor was disciplined by a multitude of regulations, and his Division asked that the patient should be subject also to a certain measure of discipline.

Dr. E. O. Lakey (Denbigh and West Flint) said he did not think anyone who had been in general practice would doubt that ensuring that messages were received before 10 a.m. was the most important help their patients could give them. He agreed that the vast majority of their patients were most helpful when they understood the situation. They asked only that patients should be given an opportunity of understanding the doctor's difficulties in order that they might co-operate.

Dr. W. Smith (Greenwich and Deptford) said that he had inquired as to what was the commonest cause of frivolous emergency calls, and the general consensus was that such calls came through clinics, where patients or parents of child patients were advised to go and see the doctor forthwith when there was no emergency at all. In his area the Divisional Medical Officer of the L.C.C. had circularized all his clinics to make it perfectly clear that when it was recommended that the doctor should be seen it must not be interpreted as necessarily an emergency, and that patients should go at the proper time. This might in many areas save a number of these emergency calls.

Dr. Wand said that action had been taken to incorporate an amendment on this matter in the Amending Bill now before Parliament.

The motion was carried.

Outstanding Questions

Dr. G. O. Barber (Mid-Essex) moved that steps be taken for a speedy settlement of a number of outstanding problems, such as the provision of health centres, payment for mileage in maternity cases, payment for urban mileage and for mileage in connexion with examination and certification of persons of unsound mind, payment for vaccination and immunization, and increase in payment for temporary residents.

He said that this was a hotch-potch of questions which the members of his Division considered should be brought forward, but he thought the purpose would be served if he asked that they might be referred to Council with a view to going to the various committees.

Dr. Wand accepted this instruction.

Dr. P. A. McCallum (Torquay) moved:

That this meeting congratulates the Council on the vast volume of work contained in its Annual Report, but regrets that so little improvement in the terms of service under the National Health Service Act has accrued from it. All Divisions are therefore urged to give Council such active support as will encourage it to stand firm in its determination to carry its negotiations with the Minister to a successful conclusion.

He said that he began to wonder occasionally when he followed the proceedings of Council whether it was emulating the individual who "lived a life of going-to-do and died with nothing done." But Dr. Dain in his speech at the opening of the present Representative Meeting had shown the mailed fist and the Representative Body was quick to put the necessary weapon in his grasp. His Division was not unappreciative of the vast amount of time the Council had expended, but it did believe there was need for more clear-cut and determined policy in dealing with the Minister. He also called for a closer liaison between Council and Divisions. Members of Council should take their constituents into their confidence.

Dr. J. A. Pridham (Council) said that there was an undercurrent of feeling in the Representative Meeting that something more should have been done. Dr. McCallum had done well to call for the enthusiastic action from the Divisions, and when that was obtained the Council could do something about it. It was no use telling the leaders to take action and to deny them troops. On Monday morning the meeting would have an opportunity of discussing the reorganization of the Council.

The Torquay motion was carried, and the remainder of the Report under "General Medical Services" was approved.

The Position of School Medical Officers

Dr. A. G. Heron (Bristol) moved that a school medical officer should send any child he considered to need hospital treatment to the family doctor, and should not, except in case of urgency, send the child to any particular hospital or particular consultant, this choice being the proper province of the family doctor in conjunction with the parents. Some representatives, he said, might think that this motion was not of very great importance, but in Bristol and other places general practitioners were being faced with a strong move to undermine the responsibility of the general practitioner for his patients. The local health departments had lost a great deal of power by this Act, and some of them were unwilling to accept this and seemed determined to establish themselves by all possible means. In Bristol, and also in the county of Gloucester, the health officers, instead of leaving the responsibility of the children to the family doctor, were trying to strengthen their hold by what were considered to be unethical measures. They had written to the south-west regional hospital board asking for medical reports on children admitted to hospital regardless of whether the children had been referred by the school medical officers or not. Gloucestershire had issued a form which had to be completed in respect of children attending schools, including secondary schools, and children under 5; Bristol asked for a report on all school-children whether treated as in- or out-patients. In neither case was there any recognition of the rights of the parents or the family doctor. A doctor desirous of a second opinion might send a child to a consultant at a hospital only to find that the child was admitted to another hospital under another consultant, or he would only learn that one of his patients had been admitted to hospital and operated on when he was asked to attend the patient after discharge. If this was allowed to continue and increase it would be all the more obnoxious, exasperating, and humiliating. Every child was now on a doctor's list, and that doctor should be the one to arrange for any necessary treatment or investigation; he had the child's records and there was no need for them to be duplicated by any authority. Infectious diseases would continue to be notified, but if the medical officer required any further information he should write to the family doctor. Three years ago the Representative Meeting passed a resolution upholding the principle that the health of the child should be the care of the family doctor, and he was confident that this meeting would pass this stronger resolution to enable the Council to help Divisions faced with these difficulties.

Dr. E. Anthony (South Essex) spoke against the motion as a general practitioner and part-time medical officer. The family doctor had the right to treat the children on his list, but there was a lot to be said for the service which the school medical service was operating. The family doctor saw whatever disease was brought to him by the intelligent parent, but the school medical officer had to see that no disease was present in the school. The two services should be integrated, but the school medical service must not be destroyed, which would happen if this resolution was accepted. ("No.") The school medical

service must be looked at as a whole, not by the odd cases referred by the school medical officer to hospital. An intelligent divisional school medical officer's arrangements were such that they were integrated with the general practitioner service; in his area no child was sent to hospital without prior intimation to the family doctor, who also received a copy of any reports; if treatment was advised it was referred to him. The school medical service kept an eye on the children, which it was not possible for the family doctor to do; teachers could refer problems which they thought were medical to the school medical officer, the service sorted out all the cases referred by the school nurse. The proper measure, in his view, was to integrate the two services more closely and not to destroy one of them.

Liaison with General Practitioners

Dr. A. Barker (East Kent) said that the liaison between the school medical service and the general practitioner was far from perfect. The circumstances outlined by Dr. Heron were similar to the experience in his area, and the Division had decided to approach the county medical officer. He asked the meeting to support the motion.

Dr. J. G. Thwaites (Council) said that he could not agree that if this motion was passed it would nullify the work of the school medical service; one must have sympathy with the school medical officer; the Education Act laid down that he was not only responsible for the inspection of school-children but for their treatment. The motion tried to make it clear that "responsibility for treatment" should be a reference of the child needing treatment to his own family doctor, and that, of course, was the right way to do it. The mover of the motion mentioned the ethical side of the problem. That had not been forgotten by the Council, and the matter was under discussion at the present time with the Society of Medical Officers of Health, the results of which he thought would be satisfactory in the right direction. To pass this motion would be helpful.

Dr. A. W. Gardner (Brighton) said that the East Sussex county authorities had taken a strong line that patients might not be sent to hospital except through their family doctor, and if a school medical officer offended in this respect he was reprimanded.

Dr. J. M. Gibson, speaking as a member of the Public Health Service, said that the motion was a strong criticism of the school medical service as a whole. Whilst at one time there was a lot said about the school medical service being an encroachment upon medical practice, that could not be said now; in fact, it was working with the general practitioner and doing a great deal of work on his behalf. If there was no school medical service the general practitioner would have a great deal more work to do. He agreed that it was much better that the family doctor should be consulted and his advice taken, but many practitioners did not want to take the responsibility for many children and were content that the school medical officer should deal with them. He felt that the resolution was going a little too far and he asked that it should be rejected.

Dr. E. C. Dawson (Derby) said that the school medical officer was one of the ever-growing number of people examining other people's children; a parallel case was that of the industrial medical officer who examined patients in an institution—that is, a factory—all patients belonging to other doctors. He hoped the motion would be supported on ethical grounds.

Dr. F. Booth (Mid Cheshire), also in support, said that most of the faults described were found in Cheshire, but they were faults not so much in the school medical officers as in the system and in the instructions to them.

Dr. A. G. Heron, in reply, said that he had inferred that there were many benevolent school medical officers and that there was no trouble in many Divisions. In others there was a danger of unlimited interference with the general practitioner with regard to their child patients, and if allowed to continue it would spread to other spheres of practice. These requirements struck at the very roots of medical ethics, but at the same time it was a question of the system.

The motion was carried.

General Practitioners and Hospital Work

Dr. W. N. Leak (Mid Cheshire) moved that the meeting should strongly protest against the steady exclusion of general practitioners from work in hospitals. The method which had been adopted, he said, was one of gradualness. First of all they were asked to meet the consultant of the regional hospital board and one of his officers, who stated that only three out of the general practitioners on the staffs of the hospitals could be recognized, and these three were given temporary contracts for two sessions a week; when the contracts were received they were for only one session a week. Doctors did not see why they should send their patients to be operated on by another doctor; the patients did not see it either; and the result was that patients were sent further afield and the whole system of cottage hospitals was being undermined. This had a profound effect on the doctors themselves. Practising in a hospital gave a doctor an added sense of responsibility; he worked in collaboration with and to some extent in competition with other doctors, and he worked under the skilled eye of other people; he lost all this when he was excluded from the hospital. The existence of a hospital in a district attracted keen men and tended to raise the standard of professional work; if the hospitals were closed to them the enthusiastic doctors would tend to congregate round the big hospitals, where they might become clinical assistants. The effect of this on country practice would be deplorable in the extreme. Lastly, there was the effect on patients, many of whom preferred to suffer rather than go to a strange doctor. Patients' feelings should be respected.

East Herts Division had tabled a similar motion, and Dr. J. S. Ross (East Herts) therefore spoke in support of the Cheshire resolution. He said that the same type of thing was happening. The general practitioners were required to work under the supervision of specialists; they were no longer able to decide which cases they were competent to deal with themselves; general practitioners experienced in midwifery were prevented from looking after their own cases in the maternity departments because they had not some specific qualification. There was a grudging proposal to allow general practitioners to serve as clinical assistants, but this practice would not be continued as the posts became vacant.

Mr. A. Staveley Gough (Council) said that this was not merely a question of instructing the Council of the B.M.A. If general-practitioner staff was to be maintained they must concentrate on hospital management committees and regional hospital boards. There was already no uncertain feeling in the Ministry, on the boards, and in hospital management committees that the quality of general practice was being upset by the total removal of general practitioners from hospitals, and certain boards were beginning to take steps to see how they could integrate the general practitioner. The hospital which had grown out of a cottage hospital could not be left entirely with a general practitioner staff unless (1) the quality of that staff was agreed by the assessing committee to be such that the practitioners not on the staff would be satisfied with the treatment given; (2) it be remembered that the boards had a responsibility to the patient, and that (3) the general practitioner should not take final clinical responsibility; he should have a specialist in control of the bed who would give him the contact with modern medicine which was necessary for his future good in medicine. The boards were now prepared to give increasing numbers of clinical assistantships of so-called senior registrarship status to general practitioners, and a large number of these posts would be available on some form of rota basis so that a wider number of general practitioners would be able to get some training in hospitals all over the country and thereby upgrade their general standing. While the Council could be asked to press this matter there must also be pressure at the periphery, and general practitioners must help.

Dr. A. Weston (West Middlesex) said that in North-west Middlesex three cottage hospitals were to be closed, and the general practitioners on their staffs would no longer be employed. A liaison committee had been formed from the six local medical committees, and it was hoped that action would be taken to resist this proposal.

Dr. G. MacFeat (Council) asked, How could the standard of general practice be improved, how could it be secured that general practitioners would carry out the work they were paid for, and would be prevented from sending patients to hospital for treatment which they were paid to give? (Cries of "Withdraw.") He would not withdraw this; he knew it was true. How could a diagnostic service be developed, or students be instructed in the commoner type of disease, except through general-practitioner hospitals? He reminded the meeting of the Association's report on General Practitioner Hospitals issued in 1946 in which it was stated that unless the general practitioner was provided with a local hospital where he could attend to his own patients the quality of the whole medical service would suffer. . . . The services of a consultant should be available, but he should not have charge of wards, and he should see both in- and out-patients only on the invitation of the practitioner.

Dr. Leak, in reply, said what he was asking was that they should be allowed to continue in hospital practice to the benefit of medicine in general.

The motion was carried.

Decisions of Medical Practices Committee

Dr. P. J. Gibbons (Liverpool) moved that, wherever the decision of the Medical Practices Committee differs from that of the Local Executive Council, the former should furnish in writing to the Executive Committee the reasons for its decision. He said that the Liverpool resolution was clear enough. It asked merely that where the Medical Practices Committee differed from the Local Executive Council it should give its reasons in writing. That was a good democratic practice on which their own Association was based, and the local committee was in the long run the best qualified to judge the local conditions. The resolution also gave him the opportunity of ventilating some opinion about the Medical Practices Committee in general. He thought that most of them, after the Act had been accepted, considered that the Committee had a part to play in helping in the distribution of doctors, and some of them felt also that it could be extremely helpful in an advisory capacity in local conditions. However, it had been found in his area that it had varied in its behaviour in many ways. For example, in its early and inexperienced days it permitted a doctor in Liverpool to go on the List—in fact, it insisted that he should go on the List—who had not any form of surgery premises in Liverpool, and who lived a considerable distance away. Its latest variation was to attempt to override the decision of the Executive Council in the choice of a practitioner to fill a vacancy in the area. On any standard that was an extraordinary claim, for Executive Councils were statutory bodies on which general practitioner opinion was fully represented, and he might say that in Liverpool in any matter affecting the general practitioners the Executive Council acted only after full and free consultation with the local medical committee. This, of course, obtained in every area, and it was one of the means which they had for protecting the freedom of the profession. It was surely a big claim to make that a central body, remote in London, should supersede the decisions of a body well informed of local conditions. He would say at once as both a member of the Association and a member of the Liverpool Executive Council that any such attempt would be resisted with all the powers they possessed.

By all means let the Medical Practices Committee concern itself with distribution. This was an appropriate and, to his way of thinking, a largely untilled field for its activities. Let it use its power in an advisory capacity and co-operation would then be assured. He believed that the community as a whole was suffering from too much centralization. Let the medical profession at least preserve as organs of freedom the Executive Councils and the Local Medical Committees which had been set up under the Act.

The Chairman of Council said that the Medical Practices Committee consisted mainly of general practitioners on whom they could rely for sound judgment. This was not an autocratic machine set up centrally and expected to be in opposition to local opinion, but it was a very valuable committee. The Ministry accepted the profession's nominations for it, and experienced general practitioners had been chosen. It was most unfortunate that the representative of any area should come forward and decry, in the way Dr. Gibbons had done, a body that was doing a good job of work. A number of complaints were at first received of the way in which the Committee's action was being directed, and two interviews with the Committee were sought and obtained and all their problems were carefully considered. It was suggested that they were not acting properly, but in the end it was found that this suggestion was baseless; in every case their action had been in the best interests of the practitioner as well as of the Service. It was unfortunate that a body should be attacked in this way on an individual grievance. He hoped the Representative Meeting would be satisfied not to act in the way Liverpool had suggested, but would believe that in the Medical Practices Committee they had a body acting in the interests of all concerned.

Dr. E. J. Warburton (Reading) moved an amendment to the Liverpool motion, making it end:

> . . . the Medical Practices Committee should give the Executive Council an opportunity of supporting their views by discussions if they so desire.

Dr. H. F. Hiscocks (South-East Essex) said that in his area they felt that the Committee had rather failed to understand local conditions. He came from an area which had a central district containing a very large proportion of medical practitioners relative to the population. Before July 5 these practitioners all made a reasonable living; since then, with a considerable fall in private practice, it had been increasingly difficult for some of them to do so. One at least became part-time assistant and finally abandoned the struggle to seek a living in industrial practice. That sort of readjustment was no doubt what Mr. Bevan intended to take place. Soon after this incident another practitioner in the same over-doctored area decided to leave. His list was one of 1,000. The Local Executive Council, with the backing of the Local Medical Committee, agreed unanimously to recommend to the Medical Practices Committee that this vacancy be not filled. Within a radius of half a mile were 14 doctors, each with an average list of something under 2,000, but the Medical Practices Committee could not see its way clear to let this vacancy go unfilled. It stated that a list of just over a thousand could not be described as a small practice. This was but another instance of the dangers of central control without full local knowledge.

Dr. Wand said that the mover of the motion and the last speaker were proposing to make things very difficult indeed. It would be recalled that a year ago they insisted very strongly on the right of practitioners to practise where they liked. At this moment the Medical Practices Committee was being faced with an increasing number of requests for closure of areas, and it was resisting this. They had to think of the younger men who were trying to get into practice. There was no very grave exception to the motion by Liverpool as amended, but he did want the meeting to bear in mind that they had a body of men in the Medical Practices Committee who were anxious to be kept informed of the position as it was at the periphery. They were, in his opinion, doing as good and as honest a job as it was possible to do. He hoped they would be assisted in trying to carry out what were really the wishes of the profession as expressed on other occasions.

Dr. Gibbons said that he accepted the amendment by Dr. Warburton. They in Liverpool felt that the Medical Practices Committee was acting in an autocratic way, and this they would resist.

The motion as amended was carried, namely:

> That wherever the decision of the Medical Practices Committee differs from that of the Local Executive Council, the Medical Practices Committee should give the Executive Council an opportunity of supporting its views by discussion if it so desires.

A series of motions concerning health centres were on the agenda, but Dr. Wand asked that all these might be referred to the Council. A subcommittee had been set up which was investigating the problems formulated in these motions, and the issues were so involved and so important that they would need proper deliberation in the subcommittee.

It was agreed to refer these motions to Council.

Consultants and Specialists

Owing to the fact that some of the representatives concerned in that part of the agenda under "Consultants and Specialists" would be absent on Monday, a section of the report under this heading was taken at this point, and the continuation of the agenda under "General Medical Services" was postponed.

Mr. R. L. Newell (chairman of the Central Consultants and Specialists Committee) said that the committee was constituted in 1948 and its formation was discussed at Cambridge last year. It was agreed that it should be a body democratically elected irrespective of membership of the Association in order that it should be truly representative of consultants and specialists throughout the country and competent to speak on all matters affecting their interests. In addition regional committees had been formed. The Central Committee was very jealous of its autonomy and began to be somewhat suspicious of the Association, and therefore he esteemed it a great honour that it should have elected him as its chairman.

The committee had spent a strenuous year. They had to form an executive committee, which had been meeting almost every fortnight. It became evident that the old Negotiating Committee could not continue its role as the mouthpiece of the consultants and that the Central Committee should undertake this function. It was also apparent that the views of consultants should be presented to the Minister through one channel and one only, and it was clear on grounds of prestige and status that the Royal Colleges and the Scottish Corporations also had a claim to participate in any discussions with the Minister. In consequence a Joint Committee had been formed. This committee had worked extremely well, and was very fortunate in obtaining the services of the President of the Association, Sir Lionel Whitby, as its chairman. There had been no disagreement between the constituent bodies. Even if there had been, there was in fact an "escape clause" which allowed any constituent body to present its case to the Minister.

Since the Report of Council the new terms for consultants and specialists had been published. He wanted to draw attention to certain items which he considered to be of vital importance. It was represented to the Ministry that the betterment factor was quite insufficient. The Minister had refused to alter this factor, and what was more ominous was his statement concerning Whitley Council machinery. The present meeting had already given a very strong expression of opinion on the question of arbitration. He regarded this as of fundamental importance and a battle which they must win.

The question of the senior hospital medical officer had caused the gravest misgivings in his committee. They realized, of course, that in this interim period a position such as this might be necessary in certain branches, but they were afraid this short-term policy would develop into a long-term policy. They were afraid that people who were fully qualified consultants would be relegated to this grade for the rest of their lives. They got an assurance from the Minister that no new appointment of this character would be made, except within a defined field, but the Minister had vacillated on this question. The Ministry had in effect issued orders that these officers should be graded as a second type of consultant. It had gone back on that, and in the new report these officers appeared under the heading of "other hospital officers." His committee had formed a subcommittee to go into the duties of these particular officers. Unofficial communications had been made to the grading committees that they should grade all people occupying posts at hospitals into three grades of consultants. He had always thought that the object of this service was to see that people giving consultant service were of a consultant grade. Hundreds of appeals against the grading had gone to the regional boards, and an Appeal Committee was set up. Fortunately he himself was not a member of the grading committee, but was later appointed by the Royal College of Surgeons as an outsider to hear these appeals; it had been possible to upgrade a very large number of people because at the appeal they had had a full statement from the man himself which was read out. The original grading committee had had no knowledge of the man's work or of its quality.

He came next to the pay-bed question. Instructions had gone round to regional boards that amenity beds should be formed in the relation of one to two of private beds, and in the future in the relation of one to each private bed. In many instances these amenity beds were taken at the expense of the fully private beds.

There were many other points he would have to put before his Central Committee at the meeting shortly to be held, and it was difficult to know which points one could discard without danger, because in the mass they produced a summation of effect. He would reiterate the advice they had already given to consultants that they should not sign their contracts until they had received some indication from the Consultants and Specialists Committee. (Applause.)

Autonomy of Central Committee

Mr. Newell then went on to move a recommendation designed to clarify the position of the Committee. Apparently, he said, the resolution passed at the previous Annual Representative Meeting had left some doubt as to whether the autonomy of the Committee was limited strictly to the sphere of consultant practice, and whether within that sphere it had complete autonomy. To make this abundantly clear he now moved that the resolution of last year be amended to read as follows:

The Central Consultants and Specialists Committee shall be an autonomous body with full powers to determine policy and action on consulting and specialist and hospital matters through the administrative machinery of the Association. The decisions of the Committee within that sphere shall not be subject to the approval of the Council or the Representative Body.

Dr. J. Ewart Purves (Bromley) moved as an amendment:

That so long as the General Medical Services Committee and the Central Consultants and Specialists Committee are autonomous, the Representative Body can no longer be considered to be the body that formulates the policy of the B.M.A.; that this situation strikes at the whole structure of the Association, and that steps should be taken to remedy it.

He said that the Chairman of Council had completely misunderstood the object of this amendment. There was no implied criticism of the Council's resolution affirming the complete autonomy of the Committee, but it must be understood that his Division at least was in some bewilderment on this subject. He sincerely hoped that they were labouring under a misapprehension and that the Council had a long-term policy which would bring a united profession into smooth waters. It seemed that there would be four autonomous bodies within the B.M.A. organization—the General Medical Services, Consultants and Specialists, and Public Health Committees, and the British Medical Guild. All these bodies which were directing policy were completely out of control of the representatives and in fact might act in defiance of them. In March last his Division after a very large meeting decided on a betterment factor, but at the Special Representative Meeting they were told by Dr. Wand that they could save their breath because the Committee had decided what betterment factor to go for and had communicated it to the Ministry and the Press. Attendance at that meeting was a complete waste of time. Dr. Wand would say that the I.A.C. had also been autonomous. Perhaps that autonomy was one of the reasons for the break-up last year. The position of consultants and specialists would be made absolutely autonomous. The shadowy Guild had as yet shown few signs of life.

The Chairman here called upon the speaker to pay some attention to the terms of his amendment.

Dr. Ewart Purves went on to say that it seemed to them in Bromley that the only relation they as an Association would have with these autonomous bodies would be as their milch cow. They would have full use of Association buildings, servants, and funds, and yet withdrawal of those facilities would not restrain them; the Association had no direct financial control over them. The only power left to the Annual Representative Meeting was to increase the annual subscription so that they might be supplied with these facilities. There had been a widespread feeling that the Association required drastic reorganization to make it into an effective fighting machine. Reorganization was going on apace, but what was the goal?

Before the meeting voted on this resolution and deprived the Representative Body of its last shadow of authority this salient question should be answered, otherwise the Bromley Division was of opinion that it was waste of time to elect and instruct representatives.

Dr. O. C. Carter (Council) said that no one in the hall was keener on maintaining the responsibilities, duties, and functions of the Representative Body than himself, but, having said that, he wanted to add this, that he was quite sure they would be doing a great disservice to the Association if they passed the Bromley motion. The proper course was to accept the situation created and to adjust the constitution accordingly. A motion by Bournemouth was also on the agenda in which the situation created was realized, and the Council was asked to look into the problem and report.

Dr. Frank Gray (Council) said that the Representative Body was a responsible body and would look at this question in the most serious and responsible manner possible. All the time, and especially since the passing of the new Act, the problems in each branch of practice became not only more serious but more complicated—problems of great detail which could not be decided without careful study or without a considerable degree of detailed knowledge. He thought every member of that meeting would wish the problems of his own particular section to be decided by those in that section, whether general practitioners, consultants, or public health officers. None of them would wish that the general practitioner should tell the consultants what to do, or consultants tell medical officers of health. If that was accepted there must be, as in fact there had always been, a great deal of autonomy in each separate section, but that did not mean in any sense that the responsibility of the Representative Body would be in any way diminished. When any section had looked at its problems and decided the line it wished to take it would come through the Council and the Representative Body to ask that the support of the whole profession should be given in presenting its case to the Ministry. That was the statesmanlike line to take. When the problems of any section were not confined to that section, and impinged on the problems of another, then they could properly be brought through the Council to the Representative Body for settlement. He hoped that the meeting would feel that the practice they had had in the past was to be continued in the future. They did not want bickerings among themselves: it was too serious. They would agree that each section, having settled its own domestic details, was entitled to look to colleagues in the rest of the profession for support.

The Chairman of Council, in reply to a question, said that he could give the assurance that the Representative Body would continue to have the power to advise. He pointed to the fact that a great part of the day and of the previous day had been spent in considering the problems of the General Medical Services Committee. The consultants and specialists required in their field autonomy to go to the Ministry. The Bromley representative had spoken as if these two committees were foreign bodies for which they had no responsibility. If they were willing to give power of action in certain directions to certain bodies, that was a common procedure of business. He suggested that a later resolution in the name of Bournemouth was a perfectly suitable one to be passed for the consideration of the Council in the next session.

Dr. W. Jope (Council) said that the Government wished to negotiate with a body representative of practitioners working in that particular service. It was very right that the British Medical Association should have that body under its guardianship. It was not a "poor relation," but very wealthy. He had taken the general practitioner side as an example, but he was perfectly convinced that the consultants' and specialists' side must have a similar set-up.

The Bromley motion was lost by a large majority.

Dr. Doris Odlum (Bournemouth) then moved:

That the Council be asked to appoint a special committee to consider and report on the situation created by the formation of autonomous bodies within the Association and their relationship to the Representative Body.

She thought this would clarify their minds and define their tion.

It was agreed to refer this to Council, and the same course was taken with a motion by Torquay, "That in order that the Association should become a potent instrument in obtaining satisfaction, the Council should bend all its energies in the coming year to arming the Association with the necessary power to enforce its demands."

Dr. W. N. Leak (Mid-Cheshire) asked whether it really followed from these Council statements and decisions that the general practitioner was considered to have no connexion with hospital matters.

Mr. Newell replied that general-practitioner specialists were represented on the Central Consultants and Specialists Committee; moreover, there was a joint committee of general practitioners and consultants surveying the whole field.

The motion clarifying the position of the Central Committee was adopted.

Representation of the Colleges

Dr. G. Catherine Evans (East Kent) moved, "That the democratically elected Consultants and Specialists Committee is the body which should represent its constituents and there should be no representation of the Colleges as such on the negotiating committee." In a very amusing speech Dr. Evans said that the College representatives were representatives only of the College Council and not of the mass of consultants. The heads of the Colleges were there for their academic distinction, not for their medico-political leadership.

Mr. Eric Steeler (Marylebone) said that at Cambridge last year he had spoken of the difficulties which might arise if the Association set up its own Consultants and Specialists Committee and the Royal Colleges and Scottish Corporations set up their own committee as well. He felt that there would be a division of consultants and specialists into two camps. Mr. Newell had told them how that difficulty had been overcome by the creation of the Joint Committee presided over by Sir Lionel Whitby.

After Dr. A. Smith (Lanarkshire) and others had joined in the debate, Mr. Newell said he wanted the meeting to think carefully before it passed the East Kent resolution. It would put him in an impossible position at this stage when they were considering as a united body the new terms and conditions of service. This resolution would destroy that body. The Joint Committee was formed for the purpose of putting forward the views of the constituent bodies to the Ministry and had never taken upon itself the power to agree to any of the Minister's proposals.

The East Kent motion was rejected.

Position of Non-teaching Staffs

Dr. Catherine Evans (East Kent), moving that it was essential that on all specialist committees non-teaching consultants and specialists should be represented at least equally with members of hospital staffs, said that it was a question of fairness. She thought it was generous of her Division to propose "equal representation" because the non-teaching hospitals did more than twice the amount of work the teaching hospitals did. There should be at least equal representation. Dr. A. V. Russell (South Staffordshire) supported Dr. Evans.

Mr. N. Ross Smith (Bournemouth), also supporting the motion, said that on the Central Health Service Committee there was no member of a non-teaching hospital staff; on the regional boards there was a preponderance of teaching hospital staffs with a very small representation of non-teachers. On the Distinction Awards Committee there was only one person who was attached to a regional board of non-teaching hospitals; on the review committees there was also a preponderance of representatives from teaching hospitals, and that might be the reason for such an unsatisfactory number of S.H.M.O. posts in the regions. On the representative side they had endeavoured in the formation of the Central Consultants and Specialists Committee to get a greater proportion, but it was noteworthy that objection was raised by the non-teachers that at the formation of the Joint Committee the non-teaching representation was reduced to two or three out of 18. This was causing great discontent among the non-teaching hospital staffs. No provision had been made in the Amending Bill for giving the staffs of non-teaching hospitals any statutory position on the medical staff committees, such

as existed with the teaching hospitals. He hoped that alterations could be made for the proper representation of the non-teaching staffs in the administration of the Service.

Dr. G. MacFeat (Council) supported the motion because the provision in Scotland for some of the consultants was not satisfactory. They were not getting an adequate voice in decisions, and the Colleges were having too much influence.

Dr. P. C. McKinlay (East Yorkshire) said that the feeling among non-teachers in his area was very strong. The chairman of the Consultants and Specialists Committee had appealed for unity, but this matter was creating a serious threat to that unity because non-teaching staffs were trying to create an association of their own. He would suggest that if B.M.A. members were to honour the position taken up at Cambridge a larger proportion of places should be allowed to non-teaching specialists.

Mr. R. L. Newell said that he hoped the meeting would not pass the resolution because it said "all specialist committees." There were specialist committees attached to boards of governors all the members of which were teachers. The regions had been asked to appoint two people, one a teacher and one a non-teacher. The Committee would be bound considerably if this motion was adopted, and he would prefer that it should be referred back for further consideration. It had wide implications, and at the moment they were negotiating to try to make the medical committees statutory bodies; if that was obtained that would be the time to consider the formation of these committees. He thought in his central committee the non-teachers were well represented; if not fully represented, they nevertheless spoke a great deal and their remarks were listened to.

Dr. Evans, in reply, suggested that five out of 18 could not be called a fair representation. The people who did the work should be the people representing the workers, and she hoped that it would be agreed to carry at least equality of representation.

Dr. Doris Odlum asked if it was not out of order to dictate the composition of a committee which was to be autonomous, to which the Chairman replied that he thought that was what Mr. Newell was trying to put forward.

The resolution was carried.

Proposed Terms for Hospital Medical Staff

Dr. T. W. Morgan (Kingston-on-Thames) moved: "That this Representative Body deplores the delay in offering final terms of service to consultants and specialists and demands that such terms be offered forthwith for their consideration." He moved this formally because these terms had now been disclosed.

Mr. A. Lawrence Abel (Marylebone) said that it was true that the substance of the motion was now out of date, but there was one matter which had not arisen and which did not arise anywhere else. Instead of saying "demands that such terms be offered forthwith," they could say now that these terms had been offered, and demand that three months be allowed for their consideration. He moved this as an amendment.

Dr. E. C. Warner (Marylebone) strongly supported the amendment.

Mr. Newell said that the terms had been issued for many months and they had been amended; people were getting anxious about very large sums of money in respect of retrospective payments. These terms had been sent to the regions, not for them to go through them again in detail—that had already been done—but for consideration as to whether they could be accepted or not and to give reasons. His committee was meeting within a week or two and would consider reports from the regions; the Joint Committee would meet to consider reports from the Colleges. They did not really require a further three months' notice to go through these terms; the alterations were not very great, and he hoped this decision would not be delayed any further.

In reply to a question, he said that the terms had been issued to boards of governors and regional hospital boards and they had been published in the *Journal*. Instructions had been given to these bodies to draw up contracts, and that was why he had reiterated the statement that no consultant should sign the contracts until he had had some indication from the Central Consultants and Specialists Committee. The boards of governors and regional boards would be powerless if the contracts were not signed. There could be delay, but to fix a time for the delay would be unfortunate. Many men were owed large sums of money and they were in difficult circumstances. If it was decided not to accept, well and good; but if they went on for three months and then accepted the terms they would find themselves in a difficult position. "Do not bind the Central Committee at this moment in terms of months."

Dr. Morgan said that one of the difficulties was that up to recently most specialists and consultants during their interim contracts had had a certain number of sessions with which they had been comparatively satisfied. The gradings being made had in a large number of cases been disappointing. Men had assumed on the terms of remuneration issued that their incomes would be a certain figure and were prepared to accept that. The review boards had been and were in process of cutting down those sessions, and consequently the income of the consultants was going to be considerably reduced. In the area of one particular regional board the gradings had not yet been published, and as the consultants and specialists did not know their gradings they could not compute their income; and how could they then accept these terms? They must have sufficient time for consideration, and therefore he supported the amendment.

Dr. R. Cove-Smith (Marylebone) said that at a meeting at Oxford a few weeks ago it was stated that 11 out of 70 had received their gradings, and great anxiety was expressed as to the position of the younger members and the registrars because the delay was causing some financial hardship. Arrangements should be speedy, simple, and more publicly known; but it was felt that any hardship that a small number of younger specialists might feel as a result of a few months' delay was considerably offset by the fact that they must have a long-term view on this point. They were aiming at producing a satisfactory status for consultants and specialists in 10, 20, or 30 years' time. "Do not let us be worried too much about sacrificing a few for a few months lest we fail to obtain satisfactory terms and status for the many in several years' time." At a London hospital last week the terms were put before a group of junior consultants, registrars, and house officers, and every one decided to turn them down forthwith.

Mr. Lawrence Abel said that the chairman of the Central Committee had misled the meeting on two points. He said that they had had months to consider this matter: the terms of service were published in the *Journal* at their own expense on June 11, barely three weeks ago; they had been reprinted in a booklet and sent to each one, also at their own expense. Mr. Newell also said that there was not much change; but there was a good deal of change. If they had read the terms and the memorandum sent with them they would see that the first change was that England was not to have a single specialist; they were going to have consultants, and they were going to have hospital medical officers, and the hospital officers were going to do the specialists' work. How did Mr. Newell fit that in with no change? Thousands of his colleagues, general practitioners and others, thought they were going to be graded as specialists; the profession had recognized them as specialists for years; but there was no specialist status in the whole of the terms of service. Both the full-time people and the part-time people were going to sign on the dotted line that they would not treat private patients without being at the whim of the lady almoner. Was that no change? Was it "no change" to have no private practice?

The consultants and specialists must have time to think again. The work had been done by specialists for years, but that grade was going to disappear. The Spens report talked about consultants and specialists, but that report was being denied in spirit, word, and deed. "We must have three months; we must give the men time to find out what was happening to the medical service of the country when the Government cannot produce a single specialist. Let us have specialists brought back into British practice, where they have always been, and let us not have their livelihood taken away from them. The Central Committee is to meet on July 5 at 11 in the forenoon, and the meeting, I understand, will start with two minutes' silence." (Laughter and applause.)

The motion, as amended, was carried.

Security of Tenure

Dr. T. W. Morgan (Kingston-on-Thames) moved to protest most emphatically at the procedure, now developing in London, of a few teaching hospitals giving notice of termination of appointments of consulting staffs at smaller hospitals which had been "designated" by the Ministry of Health. He asked that the Council should take suitable action forthwith to end this practice. He said that if this was passed unanimously it would strengthen the hands of the Council.

Mr. Newell said that they had been very much concerned about this, particularly in four hospitals in London, and had received certain assurances, but he would accept the motion with great pleasure.

Mr. Lawrence Abel moved an amendment so that the motion would read :

That the Representative Body protests most emphatically at the procedure, now developing in London and elsewhere, in the action of a few boards of governors of teaching hospitals and regional boards giving notice of termination of appointments of consulting staffs at smaller hospitals which have been "designated" by the Minister of Health, and demand that the Council take suitable action forthwith to end this practice.

Mr. Newell accepted this also.

Miss Gladys M. Sandes (Marylebone) said that the action of a regional board in ordering the closing of a hospital without consultation with the consultant and specialist staff was completely totalitarian. She wished to emphasize this unheard-of behaviour. It was scandalous that a body which was politically controlled should contravene all the elements of justice, and, what was more, get away with it.

The motion as amended was carried.

The Senior Hospital Medical Officer

Dr. F. M. Rose (Preston) had a motion deprecating the arbitrary action taken by the Regional Hospital Boards in assessing the status of the medical staffs of hospitals. This was not a vote of censure on regional boards as such, but on the general procedure of this business of setting one medical man against another in the judgment of his work. At one stage it was proposed that there might be certain gradings of general practitioners. He was very glad to say that any such attempt was resisted. Nothing has caused greater disquiet than the application of this method by which so many anomalies were created, particularly in the case of general-practitioner specialists and in some of the categories like anaesthetists, who had received no appropriate grading at all.

Mr. P. A. McCallum (Torquay) moved to add the words "and assures the Central Consultants and Specialists Committee of the Association's full support should it be decided to advise members to refuse to sign contracts." The motion was a good one, but not strong enough, and feeling was running very high. He could assure Mr. Abel that the feeling was just as high in the provinces as it was in London. Many men were alarmed at the idea of becoming senior hospital medical officers and remaining as such, possibly for the rest of their lives. It was not only an indignity, but it meant a very serious loss of remuneration—in some cases possibly £1,000 a year or even more.

The amendment was accepted, and the motion as carried read :

That this meeting deprecates the arbitrary action taken by the Regional Hospital Boards in assessing the status of the medical staffs of hospitals and assures the Central Consultants and Specialists Committee of the Association's full support should it be decided to advise members to refuse to sign contracts.

Dr. D. M. Hughes (South-West Wales) moved to instruct the Council to urge the Minister of Health so to amend the Acts or Regulations that the regional grading committees should by statute consult the medical practitioners of all classes, general practitioner or otherwise, on the merits of individual applicants for grading. When grading committees sat hundreds of miles away from the area it was very difficult for them to assess the position as general practitioners saw it. The general practitioner was the keystone on the arch poised between the patient and consultant, and he was surely the man to help the judge in assessing the merits of the consultants with whom he had worked so closely in the past. Grave injustices would never have occurred had there been experienced general practitioners on these grading committees.

The motion was carried unanimously.

Dr. Hughes further moved to instruct the Council to take immediate steps to urge the Minister so to amend the Act that specialists dissatisfied by the decisions of regional grading committees might have the right of appeal to independent appeal tribunals.

Dr. J. A. Brown (Council) thought it doubtful whether any amendment of the Act was required in order to set up these tribunals. He moved an amendment : "That an appeal committee should be set up in each region and that such committee should include among its members some of those who made the original assessment. The appellant should have the right to make a personal appeal before the Appeals Committee."

Mr. Newell said that the procedure at present adopted was that the original review committee should act as an appeal committee with the addition of two individuals, one nominated by the appropriate college and one by another review committee. He thought that Dr. Brown's suggestion was an extremely satisfactory one, and he was prepared to accept it.

The amendment moved by Dr. Brown was carried.

At this point the meeting adjourned (5.30 p.m.) until Monday morning.

MONDAY, JUNE 27

The Representative Body resumed its meeting, under the chairmanship of Dr. Gregg, at 10 a.m., following a meeting of the Council earlier in the morning. In accordance with previous arrangement, the business under "Organization" was first taken.

ORGANIZATION

Constitution of Central Council

Dr. J. A. Pridham, chairman of the Organization Committee, as a recommendation of Council, moved :

That the Representative Body approve the principle that the number of members of Council directly elected by members in the Branches and Divisions of the Association in Great Britain and Northern Ireland should be increased.

Dr. Pridham explained the changed circumstances which had induced the Council to bring about this alteration in the method of election. The first was the enormous growth in the membership of the Association ; the second was the increasing encroachment of the State upon the way of life and the pocket of every doctor. The rank and file desired to have some means of making their views and opinions felt at the centre, and the difficulty was, with very large electoral areas, to ensure that members of Council could keep in touch with their constituents.

Dr. H. G. Dowler (Gloucestershire) moved the reference back of para. 124 of the Annual Report and Section (viii) of Appendix IV of that Report. There had been a certain lack of confidence in the B.M.A. and its leaders. He thought this was unjustified, but it did seem to exist in the Branches. The real trouble had been a sense of remoteness which had led to an inability to understand the difficulties with which the Council had to contend. The alternative was increasing apathy and the possible formation of competing bodies. The Council and the Organization Committee were to be congratulated on dealing with this problem, but they had failed to grasp the essential thing, and in some respects their proposals seemed to make the position worse than it was at present. As many members of Council as possible should be directly elected by constituents which should be as small as they could be made. There should be no "back stairs" method of election. The proposals failed to meet the requirements. Instead of aiming at more areas having one member each, the report suggested several larger areas having two or more members. It would be better to delay matters than to make mistakes which would be regretted afterwards.

Mr. N. Ross Smith (Bournemouth) supported the reference back, and for additional reasons. This question [illegible]

of the Council was a complicated and difficult one. It was necessary to make the Council a stronger and more flexible instrument of medico-political action than in the past. Two factors which demanded consideration were the formation of autonomous organizations of general practitioners and specialists and the formation of the British Medical Guild. He believed that the formation of autonomous bodies was absolutely necessary, but it had two consequences. The power of the Council and of the Representative Body in medico-political matters within those spheres had largely disappeared, but all matters of common interest should be the province of the Council, and for that purpose it should have more sectional representation. It was not enough to have merely the chairmen of the autonomous committees on the Council. The Guild, which had to organize and finance collective action, made it more necessary still that the Council should contain direct representatives of the autonomous committees.

Dr. J. L. McCallum (Westminster and Holborn) felt that they were not proud enough of their Association. He supported the reference back, which meant that they reaffirmed their pride in what had been done already. The B.M.A. was the only organization which could save the profession. The danger lay in apathy in the Divisions. More seats rather than fewer were required for members directly elected on the Council by the Representative Body. Only in the Representative Meeting could the relative merits of the individuals who should be on the Council be weighed up.

Dr. S. Noy Scott (Plymouth) urged the rejection of the reference back. The Organization Committee had produced a set of recommendations. Was it desired further to delay matters before these were accepted?

Mr. H. H. Langston (Winchester) said that in the Association they needed two things: a really strong Council, confident of the support of its members, and a Council in close touch with the periphery. They had been told that the Council had much the same constitution as in 1907. The directly elected membership should be substantially increased, and in Winchester they did not think that the proposals put forward by the Organization Committee went far enough. If this motion was passed as it stood the matter would not come up for discussion until next year, and it would be two years before the new Council could be formed.

Dr. P. C. McKinlay (East Yorkshire) drew attention to some of the anomalies in the proposed groupings of Branches and Divisions for election of Council, in particular the allocation of only two seats to Yorkshire as compared with four to Lancashire and Cheshire.

Dr. R. W. Cockshut (Hendon) said that the point was whether they should abolish the two-tier method of election they had at present. Should they do away with the great deal of the power of the Representative Body to elect members of Council? Election at the periphery was often uninformed, while election by the Representative Body was informed. In two constituencies the members had not even troubled to nominate a candidate for the Council, and then they were told that these were the people who should have the power to elect the Council, while that power was taken away from the Representative Body. It was up to the Representative Body who were in touch with the periphery to elect this important part of the Council.

Dr. G. de Swiet (Paddington) supported the reference back and instanced the position in the Metropolitan Counties Branch, which would be apt to be dominated in electoral numbers by the important Marylebone Division.

Mr. G. Whyte Watson (Bradford) said that it was necessary to have a strong Council. The apathy in the periphery arose from the lack of contact of members of Divisions with their Council representatives. In many cases the representative had to cover a wide area and could not possibly be much known by his constituents. If they did not get down to smaller areas and more locally elected representatives the Council could not take decisions with any assurance that the rank and file of the profession were behind them.

Dr. F. Gray (Council) said that there were two objectives: the best men for the job, and contact between the centre and the periphery. Their forefathers seemed to have thought of the first but not of the second, and at a critical moment when the Council had to make important decisions contact with the periphery was lost. It was useless to have elections of people who were only names on a piece of paper; there must be contact and it must be maintained. Every member of Council should be *ex officio* a member of the executive committee of every Division in his area; there should also be contact between Division secretaries. The meetings should not go into details but should accept the principle so that progress could be made.

Dr. C. Watney Roe (Chelsea and Fulham) supported Winchester. There was no need to refer the matter back to Council; the rank and file would not support the Council unless it had confidence in it.

Dr. I. G. Innes (Council) said that the resolution was put before the Representative Body after very careful consideration. The position in London and the surrounding counties had been considered, but the greatest difficulty arose in the very large areas in other parts of the country.

Dr. D. L. Gullick (East Herts) said that the original motion was quite modest, but the amendment of Gloucestershire was sweeping—the reference back of this section of the Council's report. If this was passed no further discussion on the Winchester reforms could take place, and he asked that the reference back be opposed.

Dr. J. G. Thwaites (Council) said that the essential principle being debated was whether the direct representation of the periphery on the Council should be increased, and he thought the meeting would wish to adopt this principle and not refer it back for further consideration. His experience as a direct representative was that he did not receive co-operation from the Divisions, and if this principle was adopted he hoped members would do their part by attending meetings and show their appreciation of the fact that their member of Council went to see them.

Dr. S. Wand (Council) said that he came to the meeting prepared to support the recommendation, but the arguments he had heard made him feel that this should be given further consideration, because he feared the young men who made their mark in the Representative Body would not get a better chance of election. He had in mind the election of an aldermanic bench, and as the matter was so important and principles were involved he supported the reference back.

Dr. Pridham, in reply, associated himself with the tribute paid to Winchester for their interest and work in this matter. This was not a contest between the Council and the Representative Body; it was a matter purely for the Representative Body to decide. There was evidence that the periphery wanted something of this sort, and it was that which induced the Council to make these recommendations. Now the representatives could show whether that was so or not. If it was referred back the Council would not know what was wanted, and it would more or less kill it for some time to come. It was hardly likely that the Council would call a Special Representative Meeting to discuss only this question. He would suggest that the general principle should be adopted and then the details could be considered.

Dr. Cockshut, on a point of order, said that there were other methods of calling a Special Representative Meeting, to which Dr. Pridham agreed; but this was a proposition which had been considered very carefully indeed. If they liked the general principle and wanted to get at the details—"throw out the amendment and pass the original resolution."

The Chairman of Council said that the resolution was a matter of principle only. Many speakers had obscured the issue by going into detail, giving reasons for the reference back; but he hoped before that was done that the meeting would express its approval of the increase of direct representation. By referring it back on this amendment no opinion would have been expressed. It had already been agreed that the Council would have to consider the constitution of the Association in view of the establishment of two autonomous bodies, the result of which might involve some reconstruction of the membership of Council. He hoped the principle of direct representation would be accepted and the rest of the report referred back for reconsideration.

Dr. Dowler, in reply on the amendment, said that the debate had served to show that changes were needed. Dr. Cockshut's point that two Divisions had failed to make nominations was an indication surely of the apathy which existed. He agreed with Dr. Gray that Council members should visit their constituencies, but that was not at present possible, because of their size. He could not agree that there would be very much delay if the matter was referred back. It must be settled, and it was urgent and important for the future.

The Chairman pointed out that the meeting should understand the effect of passing the Gloucestershire amendment. It meant that with the exception of two constitutional changes—namely, that the chairman of the General Medical Services Committee and the chairman of the Central Consultants and Specialists Committee should be members of the Council, if not already members—the whole of the proposed constitutional changes in so far as they affected the composition of the Council were set aside for reconsideration.

The amendment was lost.

A motion was then proposed by Dr. Brown, and seconded by Dr. Russell:

That this meeting, while approving the principle of increased direct representation on the Council, refers back to Council for consideration the detailed reconstitution of Council.

Mr. Langston supported this proposal, but said that the numbers of directly elected representatives proposed were, in his view, "chicken feed." A considerable increase in directly elected members was necessary.

Dr. H. Barbara Woodhouse (Harrow) opposed the amendment on the ground that delay ought to be avoided.

On a show of hands the amendment was carried:

In favour	174
Against	116

This result wiped out a large number of motions which were on the agenda.

Agenda of Representative Meetings

Dr. R. Hale-White (Marylebone) brought forward certain proposals to facilitate business at Representative Meetings. He moved that representatives whose motions and amendments had been "grouped" or "held covered" should be given at least 48 hours' notice in writing, and on the day of the meeting should have an opportunity to meet for discussion to decide on the proposer of the motion. These and other suggestions were put forward by Marylebone to clarify debate.

Dr. Pridham thought the Marylebone suggestions might assist the Representative Meeting. Dr. J. A. Ireland (Council) doubted the practicability of the suggestions.

Mr. A. Lawrence Abel (Marylebone) urged that consideration should be given to them.

The Marylebone proposals were adopted and a proposal from Mid Cheshire for a "steering committee" for the agenda was referred to Council.

Regional Secretaries

Mr. H. H. Langston (Winchester) had a motion defining the duty of regional secretaries. He considered that the primary duty of such secretaries should be to their regions, to which they should pay regular visits and be available for liaison with divisional secretaries. It was most important that members in the regions should be kept in close touch with what was going on at Headquarters through the regional secretaries, and that the regional secretaries themselves should be well informed of opinion at the periphery. He did not believe that regional secretaries could really know what was going on if they merely went down occasionally and addressed a meeting.

The Chairman of Council said that the assistant secretaries were appointed by the Council for particular duties under the direction of the Secretary. It had been arranged that each of them should be in charge of a region; but their primary duty was to the Council, and he hoped that the Winchester resolution would not be passed in its present form, which stated that the primary duty of these secretaries was to the region.

It was agreed to pass to the next business.

Other Organization Matters

Dr. Pridham, in moving the adoption of the remainder of the report under "Organization," said that some fall in the membership might have been expected when the excitement had died down, but it had continued to rise and had now reached a record figure. A conference of honorary secretaries was held during the year which was very well attended; the chairman of that conference would be sent all the documents of the Organization Committee and asked to attend its meetings as observer. The honorary secretaries were working as well as ever they did, and on behalf of the Council he thanked them. The Council could be congratulated on the work accomplished during the year, and he would draw attention to an important document which had just been issued—"The Role of the Division." Fears had been expressed that with the formation of the autonomous bodies the Division or Branch might find its work superseded, but the reverse was true. The contact of the ordinary members was in the Divisions, and the Division must see to it that on the functional bodies there was a sufficient number of people in whom they had confidence. "So do not have a defeatist feeling about the work of the Division, study the report and make your Division more alive than it was before."

The resolution was carried.

Dr. P. W. F. McIlvenna (Reading) moved that the quorum of the Representative Body should be reduced from one-half to one-quarter. His Division felt that one-half was too high a figure for a body of this size. One of the Special Representative Meetings disintegrated, although there were important resolutions to discuss, because of this rule.

The resolution was lost.

Dr. G. W. Ireland (Lothians) moved to request the Council to make the duties of representatives more clear in the *Handbook*. He said that the instructions were not precise enough; it depended upon the interpretation of the words "so far as may be." This interpretation had led to a good deal of confusion. Many representatives asked for permission to depart from their instructions in the light of the debate, which was the right procedure, but there seemed to be some who did not realize that that could be done. In minor issues they used their own judgment, but in matters of high policy where decision was vital they felt their hands were tied. He was not putting in a plea for the abolition of Divisional instruction, but the essence of democracy was trying to find the right way through. It should be made clear to representatives that they must have their instructions, but they must be prepared to change their opinion in the light of the debate.

Dr. S. F. L. Dahne (Reading) supported the Lothians motion. It was an essential part of the democratic character of the Association. It had been laid down by Burke that no Parliamentary representative should be bound by instructions from his particular constituency. He must use, and had a right to use, his own discretion in the light of circumstances.

The motion was carried.

On the motion of Hendon it was agreed to urge the Council to take steps for the preparation and early issue of a *New/s Qualified Practitioners' Handbook*.

The Chairman of Council accepted for consideration a motion from Lanarkshire that payment of mileage be made to members attending Committees of Divisions and Branches and also certain Central Committees where a mileage grant would be appropriate and equitable. He said he realized the difficulties of remote areas.

This was carried, notwithstanding a request of Dr. Dahne that it turn it down on the ground that it reduced the Association to the level of the Boilermakers' Union.

Dr. A. Weston (West Middlesex), for the Metropolitan Counties Branch, moved that all medical members of the U.S. Army Air Force Medical Corps be elected as honorary members of the Association during their service in the United Kingdom.

Dr. J. B. Wrathall Rowe (Harrow) suggested that U.S. medical officers visiting this country in ships of the United States Navy be included.

The motion was agreed to with applause, except that, in accordance with the by-laws, the word "honorary" was changed to "associate."

Dr. W. Smith (Greenwich and Deptford) asked the Council to consider ways in which Divisions could honour members who had rendered outstanding services on their behalf. He said that his own particular Division had one member who for 40 years had rendered outstanding service to the area.

The Chairman of Council said he was prepared to look into this matter. He realized that the opportunities they had at the moment for recognizing distinguished service at the periphery were meagre.

PSYCHIATRY AND THE LAW

Dr. Doris Odlum, Chairman of the Committee on Psychiatry and the Law, moved the portion of the Report under this heading. She said that her committee was a joint one of magistrates and doctors, the latter including both psychiatrists and general practitioners. It had been at work since 1945 and had produced some memoranda of interest. Last year it produced a memorandum on the treatment of sexual offenders, the proposals in which had been received with great favour, as letters testified from all over the world. The committee also had a part to play in amendments to the Criminal Justice Bill. Other matters which it was proposing to look into included the delinquent adolescent boy, solicitation and the law, and drink and drug addiction.

The section was approved.

CONSULTANTS AND SPECIALISTS

Senior Hospital Medical Officers

The meeting then turned to the portion of the Report under "Consultants and Specialists" from the point where it left off on Saturday.

Dr. E. J. Warburton (Reading) moved:

That this meeting views with concern the creation of a body of senior hospital officers without right of appeal against their assessment to an independent tribunal.

Mr. A. M. A. Moore, on behalf of the Central Committee, said that this was the view of the committee, and he accepted the motion on its behalf.

Mr. A. Lawrence Abel (Marylebone) moved to add the words "and feels that this grade should be allowed to die out." He said that when they discussed this matter with regard to various types of consultants and specialists it was pointed out that in tuberculosis and mental institutions there was a grade of men who had never wished to become more highly qualified or to be what would be called specialists, but nevertheless they did outstanding work, and it was for these men that this category had been set up. The word "Specialist" had now been omitted. There was no such grade as that of Specialist. There were only Consultants and Junior and Senior Medical Officers. There was no mechanism whereby a hospital officer might ever become a consultant, and therefore it was felt that this grade should be allowed to die out. The public, Mr. Abel added, were losing something. What the average man in the street had had in the past was good doctoring and increasingly better doctoring. Some would say that the term "consultant" included "specialist." Very well. Then let them have it in the "Book of Words." The elimination of the specialist was a device of the Government to save money at the expense of the population. What would be the effect upon the consultant and specialist service of this country? It would mean that no man in the Service could become a specialist, or if he did he would not be so called.

Mr. Moore said that this again was already the policy of the Central Committee and had been impressed upon the Committee very strongly indeed by Sir Lionel Whitby and his Joint Committee.

Dr. Warburton, the mover of the original motion, thought Mr. Abel's an unfortunate addition to the amendment. It introduced something entirely different from the original motion.

Dr. J. C. McMaster (West Somerset) said that the average rate of remuneration offered for a senior hospital medical officer worked out at an average of £178 per annum for one session per week, which compared unfavourably with general-practitioner remuneration, though he would not agree that the latter was adequate. In his view the whole memorandum concerning hospital medical staff should be entirely redrafted.

Mr. Abel's additional words were taken as a rider, and both the original motion and the rider were carried unanimously.

Dr. J. C. Arthur (Gateshead) moved:

That tuberculosis medical officers of standing and experience should be classified as specialists and not as senior medical officers.

He said Mr. Abel had stated that the Minister had killed off the specialists. He held that tuberculosis medical officers should come within the specialist category.

Dr. T. W. Davies (Swansea) said that tuberculosis officers were men who fulfilled entirely the criteria laid down in the Ministry's memorandum. They were men of experience, in charge of beds, and held in the highest regard as consultants by their general-practitioner colleagues.

Dr. A. Smith (Lanarkshire), in supporting the motion, said that, if there was not an adequate establishment of tuberculosis service in the future, young men would not be inclined to enter that service. He quoted the pre-war figures for tuberculosis in Glasgow. New cases in the last pre-war year were 3,300, and in 1948 they were 9,981. The waiting-list in 1939 was 127; it was now 1,481. These were terrifying figures. But this service could be improved only by obtaining a reasonable establishment of senior consultants so that the men who entered it could be assured of their future.

The Gateshead motion was carried.

Dr. R. G. Cooke (Derby) proposed the creation of an intermediate grade between senior hospital medical officers and specialists, to include medical superintendents not already graded as specialists, with a salary range of between £1,500 and £2,500. He said that the administrative work these medical superintendents had had to do, especially in general hospitals, had adversely affected their claims to specialist payment. The result of the proposals which had been put forward was that quite a number of people in general hospitals would be no better off at all. The suggestion of Derby would avoid the victimization of a class of people who in the past had worked so well that they had brought municipal hospitals to the high standard in which they had entered the National Service.

Mr. Moore said he was very sympathetic to this motion, but he suggested that it should be reworded as follows:

That the salary of medical superintendents not graded as specialists be in the range of between £1,500 and £2,500.

He pointed out that the meeting had already agreed on Mr. Abel's motion that the grade of senior hospital medical officers be allowed to die out.

THE ASSOCIATION OVERSEAS

Before calling upon the Chairman of the Colonial and Dependencies Committee to present that part of the Council's report, the Chairman expressed pleasure at the presence of a number of representatives from Overseas Branches in the Representative Meeting. There were difficulties at home, but all were conscious that their colleagues overseas had difficulties and problems which perhaps were not fully understood, but he would assure them that all possible help would be given to them if they would put their problems to the Council of the Association.

Dr. J. B. Wrathall Rowe moved on behalf of the Chairman of the Committee that the report be received. He said a good deal of work had been achieved during the year. Although it became clear that the revised salary scales obtained for the medical service in East Africa were not satisfactory, the Committee decided to press on with a full-scale review of the whole situation in the light of the Spens Report and the terms negotiated for doctors in the National Health Service of this country. There were many and complex problems to be considered, and the help of an expert statistician was called in. The Colonies would have to draw their service doctors from the United Kingdom and would have to compete with the National Health Service; therefore salary scales had to be comparable. The Committee had also given careful thought to the remunera-

tion of locally recruited colonial medical officers. Negotiations were in progress with the Colonial Office, and so far a co-operative spirit had been met with in their representatives, who realized that it was of enormous importance to the Colonial Empire that they should have expert medical services.

One of the greatest problems in the Colonial Empire was the rapid increase of the population, and there was reason to believe that the results of the recent census in East Africa would lend powerful support to the contentions of the Kenya Branch contained in a memorandum which the Council had sent to the Secretary of State for the Colonies. The Council was also watching with great care the negotiations taking place on the unification of the Malayan medical service. It hesitated to express an opinion on this complex problem, but it was true to say that the unification scheme which was outlined at the Representative Meeting last year had contributed to its solution.

With regard to private practice in the Colonial Medical Service the Council's view generally was that private practice should be forbidden to Colonial Medical Service officers except in certain circumstances. It was quite clear that if private practice was not allowed in some places the medical service would not be of reasonable standing.

A number of matters not included in the Council's report were dealt with. The Council was prepared to take just as much trouble over the affairs of the many members of the Association overseas as over the affairs of members in this country. The Council was always glad to have the assistance and guidance of the members of the 53 overseas Branches, and was grateful to the officers of those Branches for their devotion to duty. Dr. E. Grey Turner's visit to the Sudan and East African Branches earlier in the year was much appreciated, and it was hoped to send a Committee member or a Secretary to the various parts of the Colonial territories. In conclusion, he added his own words of welcome to the representatives from overseas.

Dr. D. R. Belletty (Assam) conveyed sincere greetings from the tea-growing districts of India. While he was Secretary medico-political problems cropped up, and so far as India was concerned it was premature to formulate any definite and fixed policy with regard to the Indian Medical Association, which had not quite made up its mind as to its approach to the B.M.A.

Professor C. C. de Silva (Ceylon) said he would probably be the last representative of the Ceylon Branch of the B.M.A. to bring greetings. Next year one of his colleagues would be the first representative of the Ceylon Medical Association, which would be affiliated to the parent body. He thanked the B.M.A. for all the help and service given to his country during the last 62 years in manifold and diverse ways.

Dr. P. Moran (Eire) said his country had walked out of the Commonwealth with its head up and its tail up, but so far as he could see there was no desire on the part of the medical profession to set up an independent medical republic. They were deeply indebted to the British Medical Association for all the help it had given in shaping the Eire Association, and for the facilities and amenities placed at its disposal. He paid a particular tribute to the clerical staff of the B.M.A. for all the help they had given to the Eire Association clerical staff in the difficult work of reorganizing the new association.

Dr. C. J. Austin (Fiji) brought greetings from the smallest and most distant Branch represented at the meeting. His Branch was very grateful for the interest of the parent body in its welfare; that its assistance was needed could be seen by a comparison of the minimum scale of salaries drawn up by the Association with the scale actually paid in Fiji.

Dr. R. E. Anderson (Malaya) said that the Branch went out of existence during the Japanese occupation, although it held largely attended meetings during the internment. It was reconstituted after the war, and the membership increased from 278 in December, 1946, to 505 in December, 1948. One of the major questions considered by the Branch was the conditions of service: Asian members were now being paid basic salaries at the same rate as European doctors, which was fair, as the local qualification was recognized by the G.M.C. Proposals for a unified service were under consideration. He thanked the parent Association for its support and hoped that it would be continued.

Mr. G. C. Halliday (New South Wales) said that last year the Commonwealth Government passed an Act by which it was necessary for the practitioner who provided free medicine to his patients to prescribe according to the Commonwealth *Pharmacopoeia* and on forms provided by the Commonwealth Government. The profession determined that this Act was not in the best interests of the patients and refused to implement it. It was very significant that in Australia the members of the British Medical Association so firmly stood behind the Federal Council that less than 2% consented to work under the Act. The Commonwealth Government was now proposing an amendment which involved liability of a fine of £50 or three months in gaol. It was certainly likely that Australian members would need the support of their colleagues in the Home Country.

Dr. Owen Johnston (New Zealand) said that in his Dominion they considered themselves definitely a branch of the B.M.A. In fact, the official designation was "B.M.A." and in very small letters following it "New Zealand Branch." He congratulated the Council on setting up the Empire Medical Bureau, which provided a wonderful service.

Mr. A. Smith Gray (Auckland) brought the greetings of the president and over 200 members of the Auckland Division. He paid a tribute to the excellent organization of the Representative Meeting, and also added a word of appreciation of the assistant secretary, Dr. Grey Turner, who had played such an efficient part in the organization of overseas affairs.

Dr. J. Lloyd Simmonds (Queensland) said that Australia still looked on Great Britain as her home country and was proud to belong to the British Commonwealth of Nations. In Australia, with over 6,000 practitioners, fewer than 100 answered the call of the Government to enter into its scheme, and the non-adherence included non-members of the B.M.A. as well.

Dr. L. L. Davey (South Australia) said that the last two years had been anxious ones for the profession in this country. The problems in Australia and in Great Britain were in many respects similar. They were sticking to the four principles of the paramountcy of the welfare of the patient, the freedom of the doctor, the acknowledgment that in medical matters he was the official expert, and the maintenance of the doctor-patient relationship.

Dr. D. E. Thompson (Tanganyika) spoke of the great appreciation of the members in East Africa of Dr. Grey Turner's visit.

Dr. J. S. Brown (Uganda) said that in most of the Crown Colonies the service was equivalent to the National Health Service in this country, and home practitioners would know how many difficulties were attendant with such a service. They had been greatly heartened by the interest taken in their own difficulties by the parent body.

Dr. G. T. James (Victoria) said that all the branches in Australia had been described as autonomous, responsible to their own Federal Council, but they strictly observed mutual loyalties.

Dr. A. H. Tonkin, medical secretary of the Medical Association of South Africa, said that his association, though it no longer had the letters "B.M.A." after its name and had become in a sense an independent body, was fully aware of its long ties with the parent body.

Overseas Organization Committee Proposed

Mr. Eric Steeler (Marylebone) moved:

That a subcommittee be appointed to consider the B.M.A. Overseas Organization including Dominions, Colonies, and Dependencies, and to ascertain the feeling of all sections of medical practitioners and others interested.

He pointed out that hitherto the majority of doctors working in the Colonial Empire had been recruited from the United Kingdom. This situation was now altering and in many Dependencies non-European doctors were beginning to predominate. These places were not immune from racial and political currents. Some Colonies were now independent self-governing Dominions, and others were moving in that direction. The present problem was how to direct the growing national

tion into right channels. It was not possible to divorce the medical from the political aspects. One of the main effects of the spreading of civilization had been to make life duller for the ordinary inhabitant. There was need for deeper knowledge for this almost unexplored field of social study. A new policy must be devised for the profession overseas if the Association was to remain in the van of progress. He asked that this Committee might be set up to consider the whole problem, to sift facts from emotions, and weed out prejudices and partially informed opinions, and to consider whether it might not be wise to establish autonomous branches in all those areas affiliated to the B.M.A.

Mr. A. Smith Gray (Auckland) opposed this motion. He took exception to the suggestion that autonomous Branches should be set up. If this were passed it would create the impression that the parent body was finding such overseas Branches as theirs a problem and an encumbrance. He knew the proposer would say that was not the intention. Much had been heard about the periphery, and he would suggest that there was a periphery far beyond the shores of this country, and those of them who were so situated would like to feel that the link with the centre would continue as strong as ever.

Dr. R. B. MacGregor (Central Malaya) also opposed the motion. He protested against anything that might make for disintegration. They were told that the main problem which faced the Association in its overseas organization lay in those parts of the Empire where non-European doctors were likely to outnumber the others. Malaya was one of the places where this state of affairs already existed. There were already more non-European doctors than European. It was true that their interests frequently conflicted with the interests of doctors recruited from Great Britain, and that they were not immune from racial and political currents. But the B.M.A. in its present form provided the one forum where they could meet and discuss their problems on grounds of equality.

Miss Gladys M. Sandes (Marylebone) put forward the point of view of the postgraduate non-European student who came to this country. These students were not in all cases from countries where they had the opportunities mentioned by the previous speaker and where there were good relations between European and non-European doctors. These postgraduates, some of whom had obtained European qualifications and some not, were gravely concerned about the situation arising in some of their areas and were quite convinced that unless they were able to have more consideration for their point of view they would be forced to keep out of the B.M.A. The Marylebone motion asked for an inquiry, and those of them who had had some hand in the training of these people wished to put over that point of view.

Dr. D. R. Belletty (Assam) said that so far as India was concerned they thought that this matter should be kept as it was. They were quite content to let matters go on, and any changes might be misinterpreted.

Dr. C. F. Mayne (Plymouth) supported the Marylebone motion. Some of their overseas colleagues had mistaken their intentions. The Council of the Association was about o appoint a committee to go into the problem of the Colonies and Dependencies, and some parts of this problem were very wide and far reaching. Those of them who had worked on such a committee were aware of the implications and asked for the appointment of the committee which Marylebone had in view. A number of pressing problems called for a committee consisting of members who were prepared to take wide views in the solution of them.

Professor C. C. de Silva (Ceylon) also supported the motion. There was not only a serious shortage of doctors but also of teachers. The Government sent 40 to 50 doctors to this country each year who took their Fellowships, etc., but that was not enough, and he begged that they should be given internships. This was something in which a special committee could help. Ceylon would also be grateful if distinguished men in the profession would visit the country, and he wished that young graduates could go out from this country to help with the teaching and do their research at the same time.

The Chairman of Council said that he was interested to find that those who had spoken in favour had come from this country and from Ceylon, whose problem so far as organization was concerned was solved. The overseas representatives had expressed some anxiety with regard to this proposed committee, and he thought it would be unwise for this body to pass such a resolution if the people on the spot were not in favour of it.

Dr. J. B. Wrathall Rowe said that he was sorry that Marylebone had persisted in putting forward this resolution after the information he had given that morning. The motion said "A special committee should be appointed." He did not think there was any need for a special committee: all that was necessary could be done by the present committees.

Mr. Steeler, in reply, said that he had asked for a committee to go into the whole question; it should have much wider terms of reference than the Colonial Committee.

The resolution was lost.

A motion by Dr. F. E. Gould (Birmingham Central), seconded by Dr. J. A. L. Vaughan Jones (Council), that the time of speeches be limited to five minutes and three minutes was agreed to.

CONSULTANTS AND SPECIALISTS

Discussion was resumed on Dr. Firth's motion that an intermediate grade be created between senior hospital medical officers and specialists to include medical superintendents who were not already graded as specialists, and that the salary of this grade range between £1,500 and £2,500. He said that the Ministry wished to put the medical superintendent down to a salary commensurate with that of a lay secretary, which was most unjustified.

Dr. E. C. Warner (Marylebone) said that there was no doubt that the intention of the Minister was to try to drive out of the profession those who had done valuable work—medical superintendents. No cognizance was being taken of the qualifications and experience which medical superintendents and their deputies had had. They should be graded higher than hospital secretaries.

A suggestion was made that the resolution should read as follows: "That the salary scale of medical superintendents not graded as specialists be £1,500 to £2,500." The meeting accepted this suggestion and the motion in this form was carried.

Dr. W. D. Steel (Worcester and Bromsgrove) moved: "That the reference in para. 63 of the Council's report should be to group medical committees, as in a number of areas the medical advisory committee is a subcommittee of the management committee, of which none of the members are elected by or representative of medical hospital staffs."

Mr. A. M. A. Moore said that it was hoped that an amendment to the Amending Bill which was before Parliament would be moved on these lines.

The amendment was carried and was then adopted as the substantive motion.

Mr. Weldon Watts (Newcastle-upon-Tyne) moved to instruct the Association to press either for direct representation of appropriate sections of the profession on boards and committees of the National Health Service, or that medical practitioners be appointed to such boards and committees after consultation and in agreement with such sections of the profession. He said that a trusted member of the profession was nominated and elected last year to the regional board; the same member was nominated this year but was not elected, a clergyman with left-wing tendencies being elected instead. No one could think that a clergyman could adequately represent the medical staffs.

Dr. D. S. Saklatvala (West Bromwich and Smethwick), who had asked permission to withdraw a later resolution on this matter, supported the Newcastle motion.

Mr. Moore said that the Central Consultants Committee was pressing this same view on the Ministry all the time and he fully supported the motion.

The motion was carried.

Mr. Moore then moved that para. 66 of the Council's report be approved.

An amendment by Worcester that after the word "partnership" in line 3 of the fifth paragraph there be inserted, "whether with other specialists or with general practitioners,"

so that it would read, "specialists acting in partnership, whether with other specialists or other practitioners, should be entitled to have their superannuation contributions adjusted," was accepted, and carried as the substantive motion.

Domiciliary Visits to Nursing Homes

Dr. H. M. Golding (Bristol) moved a resolution regretting the setting up of regulations making a patient in a nursing-home both private and N.H.S. at the same time, and demanded that the anomaly be resolved. He said that a consultant was called to see a patient in a nursing-home, and both she and the general practitioner and the patient thought she attended under the Service; but when her account was presented it was refused, the senior medical officer stating that patients in nursing-homes were regarded as private patients. It seemed that a serious anomaly had been set up; a patient could be a private patient and a Service patient at the same time in the same place, and for the same illness. His Division suggested that it should be put right by allowing either all N.H.S. patients in nursing-homes, domiciliary visits by specialists or the charging of fees by their general practitioners.

Mr. N. Ross Smith (Bournemouth) hoped that the meeting would not approve this motion, especially with regard to domiciliary visits by specialists, because it might have a serious effect on private practice. The specialist going into the nursing-home would be a part-time specialist and dependent upon his fees for his livelihood. Those who felt that continuance of private practice was essential for the freedom of the patient and of the doctor would agree that the motion should not be accepted in its present form.

Mr. A. M. A. Moore supported Mr. Ross Smith. This matter had been fully considered by the Central Consultants Committee, who saw the danger of this proposition, and he would urge the meeting not to accept it.

Dr. Golding, in reply, thought that the sense of the motion had been misunderstood.

A motion to pass to the next business was carried.

A representative of Edinburgh moved that the recommendation to the committee in regard to domiciliary visits in nursing-homes should be extended to include all urgent medical or surgical or other cases. He failed to see why obstetric and neonatal cases should be distinguished from other medical and surgical conditions.

Mr. Ross Smith thought exactly the same objections applied here as in the case of the Bristol motion.

Here also it was agreed to pass to the next business.

Dr. J. A. Ireland (Council) moved:

That it would be advantageous to hospital medical staff committees for them to co-opt any local member of the central B.M.A. council as observer.

which was accepted on behalf of the committee.

Mr. A. Lawrence Abel (Marylebone) moved to emphasize para. 72 of the report of Council on the subject of trainee specialists and urged that consultation with medical staff committees should be made statutory. This was agreed to.

Dr. G. O. Barber (Mid Essex) moved:

Economy in hospital management should be effected firstly by a reduction in administration costs.

He said that this was brought to his notice by the consultants in a local hospital in his Division. There the cost of administration was said to be from 2% to 3% of the cost of the whole service. If the cost of the service were analysed and the amount of salaries for men working in that service were separated from the large sum of money spent on drugs, appliances, etc., this percentage might represent a quite unreasonable proportion. When they were told that cuts had to be made in hospital services it seemed reasonable that administration expenses should be cut down.

The motion was carried, and further motions were carried without discussion—namely (Chelsea and Fulham) that a list of specialists willing to undertake domiciliary consultations should be circulated to general practitioners without delay, and (Westminster and Holborn) that a proportion of the appointments which may be booked for out-patient consultation at hospitals should be reserved for urgent cases.

ELECTIONS

In the course of the meeting the results of the following elections were announced:

Chairman of the Representative Body: Dr. E. A. Gregg (unopposed).

Deputy Chairman: Dr. J. A. Brown (unopposed).

Twelve members of Council elected by the home representatives grouped in twelve groups:

Mr. L. Dougal Callander (unopposed).
Dr. P. J. Gibbons (unopposed).
Dr. Alexander Brown.
Mr. D. S. Pracy.
Dr. H. R. Frederick (unopposed).
Mr. A. Lawrence Abel.
Dr. D. F. Hutchinson.
Dr. R. G. Gordon.
Dr. T. W. Morgan.
Dr. G. W. Ireland (unopposed).
Dr. George MacFeat (unopposed).
Mr. Ian J. Fraser (unopposed).

Eight members of Council elected by all the representatives acting together:

Dr. J. C. Arthur.
Dr. O. C. Carter.
Dr. R. Forbes.
Dr. James Fenton.
Dr. I. D. Grant.
Dr. J. A. Gorsky.
Dr. J. A. L. Vaughan Jones.
Dr. S. Wand.

Surgeon Rear-Admiral C. H. M. Gimlette, R.N. (ret.), was elected as the representative of the Medical Branch, Royal Navy, on the Council for the period 1949–52.

Dr. O. C. Carter (Bournemouth) was selected by the meeting to receive the support of the Association in the election of a direct representative to fill a vacancy on the General Medical Council.

GENERAL MEDICAL SERVICES

The meeting then returned to the remaining motions on the portion of the report dealing with General Medical Services. A motion by West Bromwich and Smethwick supporting the action of the General Medical Services Committee in its endeavour to ensure that general practitioners can order stock drugs on Form E.C.10 was carried.

Dr. S. Smith (Tower Hamlets) moved:

That the time has arrived when certain measures should be taken to limit the misuse by patients of the right to change their doctor at any time, while maintaining the principle of "free choice"

This was referred for consideration to the committee.

Ex-Service Doctors and Assessment Compensation

Dr. Smith further moved:

That in place of the present arrangements whereby ex-Service doctors appeal to a tribunal for assessment of compensation to be based on pre-war earning, it should be their right to do so, if they so desire.

He said that the problems of ex-Service men in the recent war tended to be forgotten, and cited a particular case of hardship.

Dr. S. Wand (Council) said that the purpose and duty of the Practices Compensation Committee was to allocate £6 million fairly among all the doctors. Ex-Service doctors had had special consideration. The suggestion that the doctor should have an opportunity of demanding that these pre-war figures be taken into consideration was something which no other doctor was able to demand. Every ex-Service doctor who made a claim could bring forward any evidence he liked, and the Practices Compensation Committee would take into consideration every relevant factor, including his pre-war income, and if the doctor was aggrieved by the assessment he had the right to appeal to an independent tribunal. It was agreed that doctors should be allowed an adequate period of rehabilitation before they were

assessed at their earning value. He asked the meeting that their representatives on the committee, Dr. Jope, Dr. Buchan, and himself, as well as other members, should be trusted to act fairly and equitably.

It was agreed to pass to the next business.

Dr. E. O. Lakey (West Denbigh and Flint) moved:

That superannuation should not be deducted on the cost of expensive drugs supplied by rural practitioners.

Dr. Wand replied that if the expensive drugs came to the value of £100 a year the superannuation deduction was 6%, but that 6% attracted 8% of Government money.

Here again it was resolved to proceed to the next business.

Blackpool requested the General Medical Services Committee to examine the whole question of superannuation with particular reference to the lack of "cover" provided during the first ten years of service.

Dr. Wand asked that any motion of this kind might await the publication of a scheme which was being propounded to build up in units and to provide for different groups in the profession.

Range of Service

Dr. J. C. Arthur (Gateshead) moved to request the Ministry of Health to correct a misinterpretation of Regulation 6 (1) of Schedule 1 of the General Medical and Pharmaceutical Services Regulations. Recently in his area a practitioner asked the Executive council for a ruling on the question whether the giving of anaesthetics was within the range of service. The Executive council referred to the Ministry, which replied that it was.

It was agreed that this matter be referred to the Council.

At this point it was desired by one representative to move, with regard to the newly published Report on Population, "That the giving of advice on contraception should not form part of the range of service of general practitioners."

The Chairman of Council said that those present had as yet had no opportunity of studying the Report on Population. He thought it could be left to the Council to take any necessary steps, and he begged them not to deal with this matter at that meeting.

A motion to suspend standing orders to admit a discussion on this subject was lost.

Various other motions were referred to Council.

Dr. R. Cove-Smith (Marylebone) moved to call the attention of the Minister to the fact that executive councils were giving insufficient notice to the patients of doctors resigning from medical lists. He said that since July 5 there had been in the London area 123 withdrawals of doctors from the Service. In six cases the vacancies were advertised and filled; in 34 the patients were taken over by a partner, but in 83 cases the patients were dispersed among other doctors.

Dr. Wand said if Marylebone would produce evidence of any case in which this had happened it would be taken up in the appropriate way.

A motion by Gateshead to call the attention of the Ministry to the waste of doctors' time caused by the great number of unnecessary references to regional medical officers was referred to the Council.

A motion, by Chelsea and Fulham, that there should be no purchase tax on drugs, was formally moved and carried.

A motion by Lincoln, that doctors when travelling at the expense of the Ministry of Health should be allowed first-class fares, was carried.

Domiciliary Physiotherapy

Dr. P. A. McCallum (Torquay) moved that as a matter of principle it should be within the power of the general practitioner to order domiciliary physiotherapy for patients when in the practitioner's opinion this was necessary. Formerly the general practitioner could order this treatment, but now in the Western region it could be given only on the certificate of a consultant. It was becoming very difficult for some members of the public to obtain some of these services, particularly for bed-ridden patients who could not be admitted to hospital. It might be argued that there were not enough to do the work, but that was beside the point.

Dr. Wand said it would be difficult to carry out this resolution if there were not enough physiotherapists. If the mover of the resolution would be willing for the Committee to explore this possibility as the personnel became available he would be happy to accept it.

The mover agreed to make his resolution a reference to Council, and the meeting agreed to it in this form.

PUBLIC HEALTH

Dr. James Fenton, Chairman of the Public Health Committee, in moving that part of the Report of the Council, said that no official information had yet been received that local authorities were prepared to negotiate. A scale of salaries was prepared 12 months ago, and ultimately the local authorities associations were informed that unless they would begin negotiations by Feb. 28 no more advertisements would be accepted in the *Journal*. This was done, and he wished to express sincere thanks to the *Lancet*, the *Medical Officer*, the *Medical World*, and *Public Health* for taking similar action, at financial sacrifice. Only five doctors were known to have applied for or accepted positions which the *Journal* refused to advertise. Public health officers appreciated the time given to the question of medical superintendents and tuberculosis officers and asked for the same kindness for themselves. The Committee dealt with part-time salaries for practitioners at cottage hospitals, remand homes, and so on, and were in negotiation with regard to these; it also dealt with the question of equal pay for men and women in respect not only of salary but of bonus, and in almost every case where the local authority was approached the Committee was successful in securing equal pay for women. The Committee was considering the recent legislation with regard to milk.

With regard to the Report of the Working Party on Midwives, the Committee's position was that the doctor and midwife constituted a team; it did not regard the midwife as the practitioner of normal midwifery and the doctor as the practitioner of abnormal midwifery; they were a team, and they must work together. The midwife did not lose status by working as a team with the doctor, and he objected to the term "maternity nurse" when the midwife was working with a doctor. She should be called a midwife on all occasions. Finally, midwives should be trained nurses; midwifery training should be a post-graduate training.

Mr. J. Shirley Callcutt (Wembley) moved that the attention of the profession should be drawn to the undesirability of medical practitioners accepting service with local authorities on a sessional basis which would tend to enable such authorities to carry out their public health work and thus ignore the B.M.A. conditions of service for whole-time public health officers. He said that probably many of those accepting part-time work did not realize that they were defeating the object of the Association, and it showed that there was a lack of concerted action among the various branches. To pass this resolution would go some way towards showing that there was mutual interest in the various branches of the profession.

Dr. P. C. McKinlay (East Yorkshire) suggested that blacklisted authorities should not be named in the *Journal* because it gave them a free advertisement. The entry should be that of appointments which conformed to the B.M.A. scale, and all other appointments should be ignored.

Dr. Fenton said that this was a suggestion which he would discuss with the Secretary and the Editor. The Wembley motion set down what was being done; doctors were being warned not to enter into part-time appointments when these should be full-time. He would accept the Wembley motion.

The Chairman asked if the meeting would accept the motion as a reference to Council, but representatives indicated that they wished to vote and the motion was carried.

Midwives' Fees

Dr. E. C. Dawson (Derby) moved that the period during which claims for fees under the Midwives Act may be submitted be extended to six months. He said that "three months" was deceptive; where a post-natal examination was made at six weeks there was only seven weeks in which to make the claim,

and if the doctor went through his accounts every three months he might miss the time limit for this claim. The proposition emanated from a medical officer of health who had had to refuse applications which came in a few days late.

Dr. J. A. Ireland (Council) said that this question had given rise to a great deal of perturbation in his district. If the claims were a day or two late they were refused, but the work had been done and there was a definite obligation to pay. He asked whether the Clause in the Amending Bill would be retrospective and cover the cases where payment had been refused.

Dr. Fenton hoped the meeting would not accept the motion. They were successful in getting the Minister to put in the extension from two months to three months in the Amending Bill, and he did not think it would be wise to ask for a further extension. Local authorities had power to meet claims made after three months in circumstances where the doctor could not send in his bill to time and their auditor would pass it. He did not think the Amending Bill would be retrospective.

Dr. Dawson appreciated what Dr. Fenton had said but hoped the meeting would accept the amendment.

The amendment was lost, and the remainder of the Report was approved.

Institutional Maternity Services

Norwich had tabled a motion urging that steps be taken to ensure that local authorities might run institutional maternity services independently of the regional hospital boards, to which general practitioners should have access. This was formally moved by the Chairman in the absence of the representative.

Dr. N. J. P. Hewlings (Oxford) said that the motion embodied a very important principle, but it was entirely impractical and he moved that it be amended to read:

That this meeting urges that steps be taken to ensure that regional hospital boards retain existing general practitioners' maternity hospitals and beds and provide more institutional maternity facilities to which general practitioners shall have access.

Dr. Fenton said he would vote for the motion, but it concerned consultants and general practitioners and he suggested that it be referred to Council, where it would be considered very quickly.

This was agreed to.

BUILDING

Mr. L. Dougal Callander, Chairman of the Building Committee, moved that the Annual Report of Council under "Building" be received. He said that considerable progress had been made in respect of repairing, redecorating, and rebuilding the Association's House. It was anticipated that the Southern Wing would be completed by 1950, provided the necessary materials were forthcoming, and there were no strikes. It would cost a considerable sum of money, but a large income would be derived from lettings. Only one group of rooms was still requisitioned, and it was anticipated that these would be freed in a few months. It was hoped to make improvements in the Common Room and members' dining-room; the old library had been used for meetings and conferences, and as licences became easier the Committee hoped to provide the amenities for which many members asked.

The report was accepted.

The Association War Memorial

A number of amendments were on the agenda to the proposal of the Council to erect a war memorial in the shape of a fountain in the forecourt of Tavistock House. Harrow and several other Divisions asked that no further action should be taken along these lines, and that, instead, a system of educational scholarships should be set up for the dependents of the fallen. On the other hand, Hendon congratulated the Council on its decision.

The Chairman of Council, in moving the appropriate paragraph of the Annual Report, said that it had been generally agreed that the Association should establish a memorial to the members who fell in the last war. There were a number of amendments in the agenda pointing out different ways in which such a memorial could be raised. There was nothing new in them; they were all considered by the Committee, and for one reason or another had not been proceeded with. The suggestion of scholarships would mean the establishment of a very large fund, and if the capital was used the memorial would be lost. Something had already been done for the children of fallen members; several parties had been to Switzerland at the expense of Swiss doctors, the Association paying travelling expenses at a cost of £1,350. Having considered all the aspects it was decided that a visible form of memorial must be chosen. There was no better site in London for a memorial fountain than the courtyard of Association House, and the Committee offered the suggestion that a memorial be carried out at a cost of approximately £10,000, and that an appeal should be issued to members of the Association to raise that sum of money.

Dr. J. B. Wrathall Rowe (Harrow) moved:

That this meeting totally opposes the action taken by the Council with regard to the choice of a fountain as a war memorial; it requests that no further action should be taken, and suggests that the sum of £10,000 should be devoted to educational scholarships for the dependents of the fallen.

In the Council he had suggested that £10,000 was an enormous sum to expend on an apparatus for ejecting water into the air. He did not think it was a suitable memorial at all. Later the Harrow Division had met and the amendment now proposed was unanimously approved. His Division felt that so large a sum of money ought to be spent on something really useful, not merely ornamental, and that it should be chosen by the representatives and not by a body of outside experts.

Dr. R. W. Cockshut (Hendon) said that the B.M.A. House was a building of very great merit, one of the finest buildings in London. Were they going to finish it or not? As was evident from the four stone plinths at the corners of the court Lutyens left it incomplete because at the time the Association could not afford to finish it. In the past great patrons had spent vast sums of money on art. If there was no one like the Association to take their place then architects would not be able to live.

Dr. G. H. Barendt (Southampton) was against the amendment by Harrow. The Education Act, 1944, expressly laid on local authorities responsibilities with regard to the children whose parents could not afford maintenance fees at secondary schools, public schools, and universities. If they devoted a great sum of money to educating the dependents of doctors who fell in the war they would only be relieving local authorities and the Treasury.

Dr. J. A. Gorsky (Westminster and Holborn) said that his Division asked him to oppose the fountain memorial under the impression that the £10,000 was coming out of the Association funds. But he learnt that it was going to be raised by an appeal to the profession. If the meeting felt that a fountain was an appropriate war memorial apart from the question of educational grants then it was for the Representative Body to ask the Council to issue an appeal.

Dr. D. L. Little (Dudley) supported the Harrow amendment, but suggested it might be possible to provide the scholarships out of income from the money subscribed, and then, when the dependents no longer needed this assistance, the capital might be employed in erecting the fountain.

Dr. J. A. Pridham (Council) reminded the meeting that the purpose of the war memorial was to set up something beautiful as an inspiration to themselves and their successors. For that purpose a visible structure was wanted. A scholarship fund would disappear in the accounts of the Association. He hoped them think of their lovely building with its fine gates, and have something there which would remind all concerned that there were more things in heaven and earth than were expendable.

Mr. A. Lawrence Abel (Marylebone) said that in Marylebone they felt it would be in keeping with Lutyen's building if the forecourt could be made an outdoor room, covered with glass and decorated with palms. He disagreed with the proposal that £10,000 should be devoted to educational scholarships; he hoped they would have something much more worthy of the thing they were trying to remember.

The Chairman of Council said they aimed at a memorial that would enhance the beauty of the building and its surroundings. If they were going to spend £10,000 they were not going to be thrift that they would not expect something real[illegible]

memorial. Moreover, it must be something that was permanent and that would remain in the building for those who came after them. It was proposed to have a competition open to sculptors and artists. The usefulness of scholarships would quickly disappear, and already a number of years had elapsed since the end of the war.

Dr. Janet K. Aitken (Council) supported the proposal for a visible memorial which should be a permanent thing of beauty. Dr. J. A. Brown (Council) supported the idea of a fountain which would be a source of pride to the living and not an insult to the dead. Dr. H. B. Muir (Fife) opposed the fountain idea and appealed for a useful memorial. Dr. K. C. Bailey (West Somerset) felt that the sum suggested was inadequate and said that his Division recommended a subscription of £50,000. Dr. R. Hale-White (Marylebone) said the reason why a beautiful visible memorial did not appeal to more people was that they had only an imperfect idea of what was in the minds of the proposers. If a drawing of the intended memorial could be circularized it would be an advantage. Dr. Elsie Warren (Kensington and Hammersmith) supported the proposal for the education of dependents.

Dr. J. W. Hope-Simpson (Mid Herts) suggested a memorial in the shape of travelling scholarships, which would have the effect of encouraging international good will. Dr. A. Barker (East Kent) urged the formation of a charity primarily for the dependants of those who fell in the war. Dr. A. Brown (Cambridge and Huntingdon) also supported a memorial which would be for the benefit of dependants. Dr. J. A. Moody (Stratford) thought that the fund should aim at £100,000, which would be much more appropriate to the sentiment of the whole profession.

The Chairman of Council reminded the meeting that there was already a War Relief Fund to which the Association had made very generous contributions. That fund was still in existence for the help of dependants, but there were practically no applications for its use at the present day.

Dr. Wrathall Rowe, in replying, said that some speakers had suggested that after a few years scholarships would cease to be needed. In that case the use of the money could be changed. The sum of £100,000 had been suggested. This would change the situation altogether. They might under those circumstances unite a visible with an educational memorial. But he thought that if the clergy of 1840 could start a school at Marlborough the doctors of the present day could do something of the same kind.

The motion by Harrow calling for educational scholarships for the dependants of the fallen was lost by a large majority and the paragraph of the Annual Report of Council was approved.

Cambridge proposed that the war memorial should commemorate all members of the medical profession who fell in the war, not merely members of the Association, and this point was referred to Council.

The meeting adjourned at 6.30 p.m.

ANNUAL GENERAL MEETING

The 117th Annual General Meeting of the British Medical Association was held in the Grand Hotel Ballroom, Harrogate, on Monday, June 27, at 9 p.m. The retiring President, Sir LIONEL WHITBY, was in the chair.

Induction of President, 1949–50

The Minutes of the last Annual Meeting held at Cambridge on June 29, 1948, were confirmed. Sir Lionel Whitby then inducted into the Chair Dr. C. W. Curtis Bain, *M.C.*, D.M., F.R.C.P., as President of the Association, 1949–50, and invested him with the presidential badge of office. In doing so he said that Dr. Bain would enter upon a difficult term of office, but he assured him that he would have the co-operation and support of all the officers of the Association. His family had been known in Harrogate for many years, and he was now the most famous physician in this spa. He wished him good fortune during his year of office.

Dr. Curtis Bain then took the Chair and reserved any remarks he had to make until the following evening.

Balance Sheet

On the motion of the Treasurer (Mr. Moore) the balance sheet and income and expenditure account for the year 1948 was submitted and approved.

Appointment of Auditors

The motion that Messrs. Price, Waterhouse and Co. be reappointed auditors of the Association until the next Annual General Meeting at a fee of 450 guineas was moved, seconded, and carried.

President-Elect

The Chairman of Council (Dr. Dain) reported that Mr. T. P. McMurray, C.B.E., M.Ch., F.R.C.S.Ed., Emeritus Professor in Orthopaedic Surgery, Liverpool University, Consulting Orthopaedic Surgeon, Northern Hospital, Liverpool, and Royal Liverpool Children's Hospital, had been elected by the Representative Body as President of the Association, 1950-1.

Vote of Thanks to Past President

The Chairman of Council moved:

That the hearty thanks of the Annual General Meeting of the Association be given to the retiring President, Sir Lionel Whitby, for *his services as President*, 1948–9.

He said that the Association had been fortunate in retaining many of its Presidents after their term of office had expired. They had continued to take an interest in the central administration. This year the Association had made one of its greatest finds. In Lionel Whitby they had a man who was prepared to take his place in the work of the Association. He had assumed the most difficult job of Chairman of the Joint Committee representing the Royal Colleges and the Association—two difficult bodies to bring and hold together. He was accomplishing that task with great skill. Having obtained the services of so excellent a President, they hoped to keep a tight hold on him, and to see that he did not recede into obscurity. They looked forward to his continued help in the difficult times which faced the Association in the next 12 months. The Association could not be too enthusiastic in its thanks to its Past President.

The vote of thanks was enthusiastically carried.

Sir Lionel Whitby, in response, said they had made him President at a very critical time, when there were no medals to be gained whatever policy was followed. He had enjoyed being President, for many reasons. He had made thousands of new friends. He had developed a tremendous admiration for the efficiency of the Association, which he had never seen before. He had enjoyed the rough-and-tumble of the Council and of the Annual Representative Meeting. He had enjoyed also the quieter matters dealt with in committees. He had enjoyed the kindly and enthusiastic co-operation by every member of the administrative staff. He had learned the great qualities of Dr. Charles Hill and had valued his wise opinion and counsel. He had admired the *British Medical Journal* and the integrity of its Editor. All these had been great pleasures to him and had made it possible for him to pick up the work of the Association with the greatest of ease. He thanked all of them for having made his year of office so pleasurable.

The Annual General Meeting then concluded.

EXTRAORDINARY GENERAL MEETING

An Extraordinary General Meeting followed immediately on the Annual General Meeting held at Harrogate on June 27, Dr. Curtis Bain presiding.

The resolution for the alteration of the Articles of Association, as printed in the *Supplement* of June 4, p. 311, was proposed by the President, as a Special Resolution, with the exception of the proposed new Article 41 (*a*).

Dr. E. A. Gregg, Chairman of the Representative Body, moved the following amendment:

COUNCIL

Composition

The Council shall be composed of the President of the Association, the President-Elect, the immediate Past-President, the Chairman, the immediate Past-Chairman, and the Deputy Chairman of the

Representative Body, the Chairman and (during the year immediately following his period of office as Chairman of Council) the Past-Chairman of Council, the Chairman of the General Medical Services Committee, the Chairman of the Central Consultants and Specialists Committee, the Treasurer, and (during the year immediately following his period of office as Treasurer), the Past-Treasurer, *ex officio*, and of Members of the Association elected by the bodies and in the manner prescribed in that behalf by the By-laws.

This was carried, and the Special Resolution as thus amended was put to the meeting and adopted.

The Extraordinary General Meeting then concluded.

LUNCHEON TO OVERSEAS REPRESENTATIVES

Forty-four representatives of overseas branches and hosts attended the Overseas Luncheon at the Queen Hotel on Friday, June 24. After the Loyal Toast the health of the overseas representatives was proposed by Dr. H. Guy Dain, Chairman of Council. Dr. Dain apologized first of all on behalf of Sir Lionel Whitby, the President of the B.M.A., who was to his great regret prevented from attending. Dr. Dain stated that the Council was fully aware that the Association had over 10,000 members overseas. The Council was at all times anxious to do its best to represent their interests. The B.M.A. was not unimportant in the world and was always prepared to intervene on behalf of the medical profession with governments and government departments. The Colonial Office had shown itself to be much more co-operative and large-minded than certain other departments. The Council required to be kept fully informed of the problems of the overseas members of the Association, and he hoped that their branches would not hesitate to enlist the help of the parent body whenever they required it. The Council in its turn aimed to send out representatives to the branches in the Empire to establish the close contact that could come only from personal relationships.

Dr. R. B. MacGregor, Director of Medical Services of the Federation of Malaya, replied with a felicitous impromptu speech. He thanked the Harrogate Division warmly for all the hospitality that had been shown to the overseas members. He addressed a special word of gratitude to Dr. Curtis Bain for the semi-tropical weather that had clearly been arranged for their particular comfort. Overseas members of the Association were very grateful for the interest shown in their affairs by the parent body. He thanked Dr. Dain heartily for his kind words and called upon the overseas representatives to drink to the health of their hosts.

SUPPLEMENTARY OPHTHALMIC SERVICE

DEPUTY IN INVESTIGATIONS

When a complaint relating to the Supplementary Ophthalmic Service is being investigated the committee must include a professional member belonging to the same branch of the Service as the respondent. The committee contains only one dispensing optician, and if he happens to be an interested party or unable for some other reason to take part, it will be impossible to form a quorum.

The Minister of Health has therefore made the National Health Service (Executive Councils) Amendment Regulations, 1949 (S.I. No. 1120), which provide for the appointment of a deputy to any of the ophthalmic medical practitioners or ophthalmic opticians who are members of the committee, as well as to the dispensing optician, provided that the appointment is necessary to enable a quorum to be obtained.

Correction

In the letter signed "Ex-Assistant" (*Supplement*, June 25, p. 365) the phrase, "He was anxious to get things settled before July 5, 1948, and prevent anyone else coming into the area," should read, "He was anxious to get things settled before July 5, 1948, and before anyone else should come into the area."

Correspondence

Hospital Staff Terms

SIR,—I am writing on behalf of my part-time colleagues in the North-East and myself to draw your attention to a number of the provisions in the proposed terms and conditions of service of hospital medical staff (*Supplement*, June 11, p. 314) which are considered unsatisfactory.

Exceptional Consultations.—Emergency visits by part-time specialists to hospitals not included in the contract with the regional hospital board are not satisfactorily covered. These visits include calls to hospitals in charge of specialists who are incapacitated or on holiday, cases of puerperal pyrexia in infectious-diseases or outlying cottage hospitals with no obstetricians on the staff, and cases presenting obstetrical and gynaecological problems arising in hospitals not normally dealing with this class of case.

Section 6, which refers only to specialists who have no contract with the board, does not make provision for such cases; and para. 28 of the Explanatory Memorandum (*Supplement*, June 11, p. 321) is impracticable, as the time to be spent cannot be estimated. If this time, which varies considerably from week to week, is included in the maximum number of hours for which payment can be made, the service must be given without remuneration, these calls must be refused, or avoidable reduction of regular sessional time must be imposed. A general practitioner is paid £2 for a similar service.

It is suggested that fees for consultation, operation, an mileage in relation to emergency hospital visits should be n less favourable than those payable for domiciliary visits and should not be subject to the "normal maximum remuneration."

Domiciliary Visits.—It is suggested that the mileage payment should be based upon five-mile increases of radius, not twenty-mile increases, which are too great to operate fairly (Section 8 (*b*)). A fixed payment for each mile travelled to cover cost of travel and travelling time would, however, be preferred.

Obstetric Emergencies.—Inadequate provision is made for attendance upon acute obstetrical emergencies in the patients' homes or outlying country hospitals by the "flying squad." In these cases immediate attention is essential—not attendance within a few hours as in most domiciliary and hospital visits—and a high proportion of the calls come during the night. As they are of a life-saving character they should not be cramped by inclusion in the overriding maximum of "200 guineas in any quarter or 800 guineas in any year" (*Section 8 (c)*).

In view of the urgency of the summons, the time spent in resuscitation, the putting aside of more remunerative work at short notice during the day, and the frequency of night calls the proposed scale of remuneration is inadequate (Section 8 (*a*) (i)). An adequate travelling allowance should be made and a reasonable fee should be paid for time-consuming resuscitation as well as for operative procedures.

This letter is sent with the concurrence and support of m colleagues, Professor Farquhar Murray, Mr. Harvey Evers, M Frank Stabler, Mr. Linton Snaith, Mr. T. G. Robinson, S F. J. Burke, and Mr. Bryan Williams.—I am, etc.,

WILLIAM H[illegible]

Newcastle-upon-Tyne.

SIR,—I feel strongly that the terms should not be agreed unt (1) there is proper security of tenure; (2) there is assurance that, in future, regulations will not be introduced to Parliament before the profession have had an opportunity of expressing their opinion. And, moreover, all other points of difference must be agreed *before* permanent contracts are signed.

Security of tenure should be until an agreed age, terminable only for misconduct or incapacity (from some all-in opinion of the position of consultants and specialists under the [illegible] Health Service Act (*Journal*, May 1, 1948, p. 849). The number of sessions should be in accordance with the wishes of the entrant and should be altered only by [illegible]

All regulations regarding [illegible] referred for comment to the Joint Co[illegible]

o Parliament (Annual Report of Council (24) (15), *Supplement*, April 2, 1949, p. 174). Also, quoting from counsel's opinion ited above:

"One of the most unsatisfactory features of the Act is that many of the important matters arising under it are not enacted in the body of the Act, but are left to be governed by regulations. The Minister has very wide powers to make regulations, and is not under any statutory obligation to consult the medical profession before he makes such regulations. . . . I advise that the Minister should be approached with a view to securing an amendment which provides that Section 1 of the Rules Publication Act, 1893 (or a suitable modification thereof), should apply to regulations made by the Minister in future.

"Under Section 1 of the Rules Publication Act, 1893, a Minister is required (*inter alia*) to give forty days' notice in the *London Gazette* of his intention to make regulations. Any public body may inspect the draft regulations and the Minister is required to consider the written representations of any public body interested before he makes the regulations."

A reminder of the Minister's power is in the Forms of Contract (*Supplement*, June 11, pp. 320 and 321): ". . . subject to the terms and conditions of service *determined from time to time by the Minister of Health*" (the italics are mine).

No one would say that there are no advantages to the community and to the profession in the stated terms and conditions, but if we are to be a happy profession able to give our best service to our patients and, in future, if the best citizens are to be attracted into our profession, surely this will be helped by the knowledge that entrance gives a proper security of tenure, and by the knowledge that there is an agreed opportunity for examination and for comment of intended alteration to the regulations by the Minister before submission to Parliament.

Except for those who can find a living entirely *outside* the hospitals among private patients, we are absolutely in the hands of the Ministry of Health both for our private and for our national work—in fact, for our very livelihood. Under such circumstances good intentions, however genuinely intended, must not be accepted. It is absolutely necessary to have the binding document expressed in no uncertain terms.—I am, etc.,

Kidderminster, Worcs JOHN W. STRETTON.

SIR,—It is stated (*Supplement*, June 18, p. 331) that the published terms and conditions of service of hospital staff represent the limit to which the Joint Committee has been able to secure concessions by negotiation.

The terms define senior hospital medical officers as those senior officers performing clinical duties who are not of consultant status but are not registrars. No assurance is given that the grade will be reserved for certain exceptional appointments; instead, there is merely some word-play in para. 8 of the Explanatory Memorandum.

Letters to the daily press indicate that the majority of those practising as specialists have been "assessed" only as senior hospital medical officers. This being so, their grading is not in accordance with the definition. In the face of general policy the appeal machinery is unlikely to affect the result much, and even less since it is worked by the original review committees plus only two new members, one of whom is engaged in similar review procedure in another region.

The conditions under which negotiations of the terms of service were conducted precluded the disclosure of unfavourable trends. If, however, the proposed application of the terms were made known and seriously disapproved, the Joint Committee surely need not have proceeded further; if this were not made known the present position is an evasion and a breach of good faith. It need not remain so after the meeting of the Joint Committee on July 5.

Difficulty and dissatisfaction are bound to result from attempts to assess the worth of individuals, but grading of appointments in terms of remuneration should be a comparatively simple matter. It is the accepted method in almost all large organizations. In the case of the Health Service, which has largely abolished alternative sources of income, the only fair index is the full value of the appointment to the community served. On this basis the reduction in status and remuneration of many former specialists is indefensible.

Distinction awards are a further likely cause of trouble. If appointments are given their fair comparative value, there should be no need for additional payments. In any case, the total remuneration of the individual will in time come to be attached to the post itself and the most suitable be chosen to fill it. This might as well be recognized, and attention concentrated on the one thing that matters—a fair range of payments throughout the Service.—I am, etc.,

Holt, Norfolk. S. W. DRINKWATER.

Grading of Hospital Staffs

SIR,—The local results of the grading of hospital staffs appear to the undersigned completely puzzling. Remembering examples which we had all known of the patchwork character and autocratic set-up of the old health services, we felt justified in expecting better things—first, in co-ordination, and secondly in democratic administration.

Among the decisions which have been made, for example, we do not see any logic in one which gives no higher grade to a senior resident who has a higher degree and takes charge of the hospital in the absence of the medical specialist than to a casualty officer; or in another which gives lower grading to the medical trainees than to the surgical ones, though their qualifications, work, and responsibilities are, to any reasonable observer, equivalent.

In the second place, we, on whose work the Service depends, were not told what our own hospital grading committee recommended; we do not even know the composition, far less the principles, of the regional grading committee. Even our specialist staff have been heard to say that the regional board is a remote body on which local representation is inadequate.

We feel, as more and more workers are feeling, that in this, as well as in other matters, some way must be found of establishing contact between people in offices and people on the job—for example, candid formal reports to individuals on the progress of their work and on the reasons for their grading; representation of the resident staff, in either executive or observer capacity, on the committee which decides their fate.

Without some such changes our cynicism will increase; and cynics cannot be good doctors.—We are, etc.,

FOURTEEN HOSPITAL RESIDENTS.

Grading of Specialists

SIR,—The Council of the Regional Hospitals' Consultants and Specialists Association (Non-Undergraduate Teaching Hospitals), of 45, Lincoln's Inn Fields, London, W.C.2, would be glad to receive from consultants and specialists who are dissatisfied with their grading by the regional hospital board particulars of their case, a copy of the appeal they have lodged, and its result when known, in order that they may estimate how widespread the problem is. It is not the intention of the council to take up individual cases, but to deal with the matter as one of principle.—I am, etc.,

The Regional Hospitals' Consultants and Specialists Association (Non-Undergraduate Teaching Hospitals), 45, Lincoln's Inn Fields, London, W.C.2. NIGEL CRIDLAND, Honorary Secretary.

Specialists: The Minister's Intention

SIR,—At the present time the profession is considering the terms and conditions of service of hospital medical and dental staffs (*Supplement*, June 11, p. 314). In the *Journal* of June 25 the North-West Metropolitan Regional Hospital Board advertised for nineteen specialists in various branches of medicine, surgery, pathology, etc., yet only three of these were part-time and sixteen were full-time appointments. A number of these appointments were in hospitals which were under the county councils of London and Middlesex prior to the appointed day, but others were in old-time voluntary hospitals in the West Herts and Bedfordshire areas.

In view of the repeatedly expressed promises of the Minister to allow private practice to continue for specialists, and in view also of the present Amending Bill, which undertakes not to introduce a whole-time salaried service by regulation, it seems most unfortunate that young specialists are being offered

only full-time appointments and have such little choice of part-time posts. Is the ultimate intention of the Minister and of his regional boards not made clearer than ever?—I am, etc.,

London, W.1. E. C. WARNER.

Mileage

SIR,—At the S.R.M. on March 29 (*Supplement*, April 2, p. 209) both Dr. Wand and Dr. Pearce remarked during the discussion on mileage that they wished speakers had come forward with their facts and figures when the Rural Practitioners Subcommittee was collecting information. I am therefore tempted to ask what information was sought by the committee before it recommended the 3s. single payment per mile (outward) over two miles for each maternity case booked in rural areas.

Be that as it may, I have two very serious criticisms to make: (*a*) that it is wrong in principle to take money from the central mileage fund to meet these payments; (*b*) that the suggested payments are insufficient, and based on an unfair method of calculation.

Let me deal with (*a*). Under the general practitioner service of the N.H.S. there are two different services side by side—viz., (1) general medical services, and (2) maternity services. Payment under (1) is based on a capitation fee per patient on the practitioner's list, and is paid out of a central pool, while payment under (2) is made under contract for work done and varies according to how much service is rendered, and in England according to whether or not the practitioner's name is on the obstetric list. Moreover, the money for this purpose does not come from the central pool and must therefore come direct from the Exchequer. That being so, there is no reason why this precedent should not be followed in regard to mileage payments for maternity work, for mileage is also done under contract. Indeed, if a proper mileage fee is paid the drain on the central mileage fund will be so great (as my figures at the end of this letter prove) that it will be necessary to adopt this procedure.

The rural practitioner can easily prove that he does more work per case than the average urban practitioner and that he is therefore entitled to extra payment. This argument has nothing whatever to do with the question of hardship or with small lists; it merely deals with a reasonable demand—equal pay for equal work.

To conclude my argument under this heading I would like to draw attention to the following facts:

(1) Under the Maternity Services (Scotland) Act, 1937, local authorities paid mileage fees under two methods, the practitioner being left to choose either method of payment. This payment had therefore no connexion with the N.H.I. mileage fund.

(2) Under the present local authority midwives scheme, where a practitioner is called in by a midwife he is paid an appropriate mileage fee by the authority.

(3) When the question of mileage was under discussion no mention was made of mileage for maternity cases. The first indication that mileage for maternity cases was included in the central mileage fund was made by Dr. Wand at the last S.R.M.—a very strange affair.

I therefore contend that the [illegible]ion of maternity mileage has not been properly investigated and that it is quite improper to deduct money for this purpose from the central fund.

Now let me deal with (*b*). The only good thing I can see in the recommendation by the G.M.S.C. is that the rural practitioner's right to be paid a mileage for maternity cases has been established. In every other respect I can only level bitter criticism.

In the first place their recommendation is quite pointless so long as the money for this purpose is deducted from the mileage fund. As I put it at the last S.R.M., it simply means that money is taken out of one pocket of the rural practitioner and put into another pocket. There was no need to make any representations to the Ministry about that. Indeed, I am sure it was ill-timed and ill-considered to take this step before the position had been clarified or properly investigated.

In the second place, the sum of 3s. recommended is hopelessly inadequate. It is not enough to pay for more than a fraction of the extra expense incurred by the rural practitioner attending the case. Compare it with the payment (which itself was inadequate) paid by local authorities twelve years ago under the Maternity (Scotland) Act, when car expenses were much less. The practitioner had the choice of being paid either (*a*) a composite sum of 6s. (outward) per mile over two miles for each case, or (*b*) at a rate of 1s. 6d. per mile (outward) over two miles for each special visit to the patient's home, and at one-third of that rate where the visit was made in the course of the daily round.

I chose method (*b*) for obvious reasons, and I will now give you my figures for 150 consecutive cases, which are therefore irrespective of locality and whether the service was a complete service or not:

(1) Total number of non-mileage cases = 76.
(2) Total number of mileage cases = 74.
(3) Total mileage for mileage cases = 326 miles.
(4) Total mileage eligible for payment = 178 miles.
(5) Total payment received by me = 178 × 1s. 6d. × number of visits = £124 13s. 6d.
(6) Total payment which would be received by me under the scheme put forward by the G.M.S.C. (from the mileage fund) = £26 14s.

Need I say any more, except that my books are open for inspection if any doubts are entertained in regard to my figures?—I am, etc.,

Auchtermuchty, Fife. HUGH B. MUIR.

*** The Secretary of the Association writes: When the Ministry recently agreed to increase the mileage fund from £1.3 million to £2 million, it was agreed that the latter amount should include mileage payments in maternity cases.

Mass Resignation

SIR,—It is very evident from the letters published recently in the *Journal* and motions submitted from many areas of the country that there is grave dissatisfaction with the terms of service and remuneration of general practitioners. Nearly a year has passed since the inception of the Act, and there has been no response from the Ministry to repeated requests to rectify these gross injustices. It is clear that negotiation with the present Ministry is hopeless.

A large majority of practitioners are impatiently waiting for a lead from the Council of the British Medical Association and I would suggest that, through them, meetings be called throughout the country at a very early date to determine our immediate line of action. Let those in favour of a mass resignation come into the open by actually giving in their signature, accompanied if need be by a substantial cheque.

I am, etc.,

Birmingham. G. A. POWELL-TUCK.

Withdrawal of Service: *Correction*

SIR,—I was misquoted in a certain London daily paper as having said that some doctors in my area feared physical violence if they resigned from the Health Service. This is wholly inaccurate. What I said was that I had been told that in certain industrial areas doctors feared physical violence if they refused to treat their patients under the National Health Service.

In my own Division of East Norfolk the doctor patient relationship remains good, and many patients have expressed their dislike of the National Health Service. I therefore write hurriedly to correct any shadow of an impression that we doctors in Norfolk have any such fear.—I am, etc.,

Aylsham, Norfolk. A. G. HOLMES.

Association Notices

MEDICAL STUDENTS' PRIZE ESSAY

The title for the Medical Students' Prize Essay for 1949 is "Clinical Teaching in Relation to the Practice of Medicine." The closing date for entries is Dec. 31, 1949. Those wishing to enter the competition should write to the Secretary of the Association for a form of application.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JULY 9 1949

SIR WILLIAM OSLER

BY

Sir ARTHUR S. MacNALTY, K.C.B., M.A., M.D., F.R.C.P., F.R.C.S.

"We are often made to feel that there is another youth and age than that which is measured from the year of our natural birth." These words of Emerson's come to one's mind in this centenary year of Sir William Osler's birth. For his teaching and influence are ever-present and in his lifetime he never grew old.

William Osler, the youngest and sixth son in a family of nine, was born on July 12, 1849, in a parsonage at Bond Head, Tecumseth County, Canada. He came of Cornish stock. His father, the Rev. Featherstone Lake Osler, married Ellen Free Pickton in 1837, and they went out to Canada from Falmouth in the same year. Mrs. Osler died in 1907 in her 101st year.

Work on Zoology and Physiology

William's schoolmaster, the Rev. W. A. Johnson, at Weston, near Toronto, introduced him to the study of biology and geology and to the use of the microscope. At 18 years of age Osler began to describe and enumerate the *Diatomaceae* of Canada, and his interest in biology was stimulated further by Dr. James Bovell when he entered the Toronto Medical School in 1868. He published a number of original papers on this subject. In 1870 he became a medical student of McGill University, Montreal, where the clinical opportunities far exceeded those which Toronto then afforded. He graduated M.D. in 1872, and in 1872–3 spent fifteen months in the Physiological Laboratory, University College, London, working at physiology and histology under Professor Burdon-Sanderson. Here he made an important contribution to scientific knowledge by describing the form and movement of the blood platelets, "the third element of the blood." It was Osler who first saw these bodies in the circulating blood, and his observations were presented before the Royal Society by Burdon-Sanderson in 1874. Afterwards Osler published several papers and lectures on the blood, including one on the development of blood corpuscles in the bone marrow. All this work established his reputation as an original investigator.

After obtaining the L.R.C.P.Lond., and visiting Berlin and Vienna, Osler returned to Montreal in 1874 and was appointed Professor of Institutes of Medicine to teach physiology and histology. As professor of physiology in the Veterinary College, Montreal, he also worked at comparative pathology. In 1878 he was elected physician to the General Hospital, Montreal, and immediately afterwards left for London to take the M.R.C.P. examination and to pursue three months' clinical study at the chief teaching hospitals. In addition to clinical work he did an extraordinary amount of original investigation in biology, physiology, and pathology during these years at Montreal. The call to Philadelphia to be professor of clinical medicine in the University of Pennsylvania in 1884 marks the end of Osler's investigations as a pure scientist in the fields of zoology and physiology. As W. T. Councilman said: "He could easily have become a great scientist, but he chose the path which led to the formation of the great clinician which he became: a worthy associate of the great men who have made English medicine famous."

Productive Years in Baltimore

In 1884, together with Clifford Allbutt, he was elected a Fellow of the Royal College of Physicians after the shortest possible period of probation. In the following year he delivered the Goulstonian Lectures to the College on malignant endocarditis, which contained the first comphrehensive account of the disease in English. At Philadelphia he increased his reputation as physician and teacher, studied malaria, and wrote on the cerebral palsies of children in addition to contributing numerous articles to textbooks and medical journals. The Quaker City would have fain kept Osler, but this was not possible. In 1888 he was offered, and accepted, the chair of medicine in the new Johns Hopkins University, Baltimore. Here he built up a great medical school which became famous not only in America but throughout the world. He devoted special attention to the organization of the Johns Hopkins Hospital, where he was physician-in-chief. From an extensive experience of medical schools in two continents Osler welded together the best features of British teaching and of the German clinics. He revolutionized medical instruction in North America by introducing the individual bedside teaching of students, who as clinical clerks had free access to the wards and patients in a clinic under a director with highly trained assistants and laboratory equipment. Osler indeed desired no epitaph other than that "he taught medical students in the wards."

Dr. Welch, the Professor of Pathology, collaborated with Osler in this pioneer work. When Dr. Welch honoured me with a visit in Whitehall in 1920 he spoke with feeling of those happy and productive years with his colleague and friend in Baltimore.

In 1892 Osler gave to the world his famous *Principles and Practice of Medicine*, used by students all over the world and translated into French, German, Spanish, and Chinese. As Harvey Cushing, his biographer, wrote: "The volume, indeed, was what might be called a practical pathology in which were given the results of modern investigation, microscopical, bacteriological, and chemical. On this foundation was built up the symptomatology and diagnosis of disease. . . ." Osler adorned his textbook with personal references to his vast clinical experience, and attractive allusions to personalities, ancient and modern, in illustrations of symptoms and treatment.

On Feb. 4, 1892, the day of its publication, Osler, with a copy under his arm, walked into a house in Baltimore where Mrs. Gross, the widow of Dr. S. W. Gross, his friend at Philadelphia, was staying, and threw the volume into her lap with the words: "There, take the darn thing! Now what are you going to do with the man?" They were married on May 8, Osler then being 42 years of age, and after a visit to Canada and England settled down in No. 1, West Franklin Street, Baltimore, where on Dec. 28, 1895, their son Edward Revere was born.

Grace Revere Osler was descended from Paul Revere, the hero of the famous ride and a distinguished silversmith and copperplate engraver. Witty, wise, and eminently practical, she was a devoted helpmeet to Sir William, entertained his friends and students, lightened the burden of his constant labours, and made their homes at Baltimore and Oxford a Mecca of hospitality and good will. Lady Osler had great personal beauty in youth, and in old age retained her wonted charm. Under a dignified presence—she was often compared to a duchess—she had the kindest and most generous of hearts. It was an ideal union, and at a farewell dinner given to Osler by the profession of the United States and Canada in 1905 Osler said: "Of the greatest of all happiness I cannot speak—of my home. Many of you know it, and that is enough." He was elected a Fellow of the Royal Society in 1898.

In 1904 Osler attended the Annual Meeting of the British Medical Association at Oxford and received an Honorary D.Sc. from the University. His former teacher, Sir John Burdon-Sanderson, the retiring Regius Professor of Medicine, asked him to accept nomination as his successor. Osler at 56 was feeling the strain of his over-busy life at Baltimore, and when he cabled to his wife on the subject she at once replied, "Don't procrastinate; accept at once." They left America amid universal regret and came to Oxford in 1905, eventually to reside at 13, Norham Gardens, which soon became known as "The Open Arms."

During the Philadelphia and Baltimore periods other universities had offered Osler appointments of distinction. His *alma mater*, McGill, asked him to return to Montreal on at least two occasions. Harvard thrice offered him chairs of medicine. In 1895 New York City offered him a university post. In 1900, on the invitation of E. A. Schäfer and others, he actually became a candidate for the chair of medicine at Edinburgh, but withdrew on account of pressure from all sides to keep him at Baltimore.

Activities at Oxford

At Oxford the Oslers were at once plunged in all sorts of activities—social, professorial, and professional. Although elected a student of Christ Church, the College of two of his favourite authors, Richard Burton and John Locke, Osler's tireless energy could never allow him to lead a life of scholarly ease. He was active as physician to the Radcliffe Infirmary, giving ward demonstrations to students and practitioners. He promoted and extended the work of the Oxford Medical School, was Master of the five-centuries-old almshouse at Ewelme, curator of the Bodleian (University) Library, where his profound bibliographical knowledge and love of old books was of great value, at one time member of the Hebdomadal Council which governs the University, President of the Oxfordshire Association for the Prevention of Tuberculosis, one of the founders and the first President of the Section of the History of Medicine of the Royal Society of Medicine—the catalogue of official duties is almost an endless one. He served on two Royal Commissions, and throughout England, Wales, Scotland, and Ireland was in constant request to deliver lectures and addresses at hospitals, universities, and medical societies. He was often called into consultation not only at Oxford but all over the kingdom. With it all he found time for countless unrecorded acts of kindness to others just as he had done in Montreal, Philadelphia, and Baltimore.

In 1906 Osler delivered to the Royal College of Physicians the Harveian Oration, "The Growth of Truth, as Illustrated in the Discovery of the Circulation of the Blood," and the Lumleian Lectures in 1910, on angina pectoris: in 1908 he gave the Linacre Lecture at St. John's College, Cambridge: in 1919, as president of the Classical Association, an office held for the first time by a practising physician, he gave an eloquent address on "The Old Humanities and the New Science."

The *Quarterly Journal of Medicine* and the Association of Physicians of Great Britain and Ireland came into existence in 1907 largely as the result of Osler's initiative and support.

He had been a book-collector for many years, and his superb library contained many *incunabula* and first editions of scientific and medical works. For over five years his

scanty leisure was occupied in preparing the *Bibliotheca Osleriana*, a bio-bibliographical catalogue of his library. It was successfully completed and published in 1929 by his cousin, Dr. W. W. Francis, with the collaboration of R. H. Hill, of the Bodleian, and Dr. Archibald Malloch, now librarian of the New York Academy of Medicine. The library itself was bequeathed with an endowment to McGill University, Montreal.

It has been possible here to mention only the more important of Sir William's writings. His published books, papers, lectures, and addresses covered an extremely wide range and mounted up to more than a thousand, as can be seen from the classified and annotated bibliography by Dr. Maude E. Abbott (Montreal, Canada, 2nd edition, 1939). "So wide are they," wrote Sir Humphry Rolleston, "that any writer, especially with a new idea, observation, or historical subject, would be well advised to find out before publication what Osler may have said upon the subject." His literary style was delightful; adorned with wit, epigram, and historical allusions, and all he wrote possessed the merit of clear exposition. These features are well displayed in his essays, *Aequanimitas* (1904) and *An Alabama Student* (1908). Sir William Osler was the pre-eminent type of the scholarly physician.

Thus, although Osler had accepted the Regius Chair as a relief from overwhelming pressure, his public activities expanded instead of diminishing. In the Coronation Honours of King George V, in June, 1911, his outstanding services were recognized by a baronetcy. Subsequently he was sounded on whether he would accept a peerage, but he declined.

The War Period

The war of 1914–18 came and added to his labours. He was an honorary colonel and a member of committees at the War Office, where on medical questions, such as the establishment of special hospitals, his advice and suggestions were invaluable. He was also on the committee concerned with the Medical History of the War and on the War Reports Committee. He rendered important services to the Canadian Army Medical Corps. As consulting physician he visited regularly the Duchess of Connaught's Red Cross Hospital at Taplow, Beachborough, the Heart Hospitals at Hampstead and Colchester, and the American Hospital at Paignton. Later he visited nearly all the American hospitals in the south of England. At these visits he renewed acquaintance with many of his old friends and students. On the receipt of a cable from an anxious parent he would visit any hospital in England to see a Canadian or American soldier and reply that he had seen that everything possible was being done.

Sir William said at a farewell dinner on May 2, 1905, in New York, that he desired "to be ready when the day of sorrow and grief came to meet it with the courage befitting a man." Noble words fraught with sad premonition. On Aug. 30, 1917, their gallant son, so full of life and promise, died of wounds in Belgium. That very night his stricken father wrote: "Poor Grace! it hits her hard; but we are both going to be brave and take up what is left of life as though he were with us."

Brave indeed was the face they presented to the world. They carried on in the same way, with lavish hospitality, the promotion of cordial relations between North America and England, and a host of medical activities. Only those who knew them well realized the sorrow that lay beneath. Sir William's hair grew white, his face was lined with care, but he continued to work for humanity. His seventieth birthday in 1919 called forth an outburst of universal affection. The medical journals in Great Britain and the Dominions and in the United States issued special "Osler Numbers," and from near and far people vied with one another in paying him loving tributes. A memorial in two volumes, containing contributions by a number of his old friends and pupils from both sides of the Atlantic, was presented to him by his brother Regius of Cambridge, Sir Clifford Allbutt, at the Royal Society of Medicine. The Oxford Medical Graduates Club entertained Sir William at a dinner, and in reply to the enthusiastic toast of his health he said: "I have worked hard all my life. There must be good rubber in my arteries or I should not now be among you still working at three-score years and ten." But even then Mr. Great-heart's course was nearly run. In October, 1919, he fell ill with influenza, and broncho-pneumonia supervened. In bed he read and wrote. His last published paper was a review of *Sir Victor Horsley's Life*, by Stephen Paget, for the *Oxford Magazine*. He kept careful notes of his own symptoms and, cheery as he strove to be to his wife, doctors, nurses, and visitors, he knew that the call had come to cross the River. "I smell the mould above the rose," he said, quoting Thomas Hood's *Stanzas*. The end came in the afternoon of Dec. 29. There was an impressive service in Christ Church Cathedral, Oxford, on Jan. 1, 1920, when men and women gathered from all parts of the kingdom to pay their last tribute to the beloved physician. His ashes, mingled with those of Lady Osler, who died in 1928, repose in an urn in the Osler Library of McGill University, surrounded by the books so dear to him.

William Osler departed from the world leaving behind him the memory of a great physician, a physician of two continents, an inspiration to British, Canadian, and American medicine, a friend of young and old. His teaching and work are an ever-abiding presence not only to those who knew and loved him but to future generations.

OSLER AT OXFORD

BY

Sir CHARLES SHERRINGTON, O.M., G.B.E., F.R.S.

Osler at Oxford! The impression left upon me is vivid enough, although I feel it far from easy to convey. It had its different sides. My privilege was to join him as a colleague in the teaching when he was still relatively a new-comer to the place. I think he regarded his chair—the Regius Chair of Medicine (attached to Christ Church)—as legitimately to be treated as a sort of sinecure; its very stipend was then rather beggarly, and Osler sometimes did not scruple to say so. He looked upon what was expected of him, not, I fancy, as in any ordinary sense a part of the routine teaching of medicine, but rather as a focal point whither to draw together the scattered strands of tradition pertaining to an ancient Faculty, some of them beginning to wear thin. I think he felt what was incumbent on him was to maintain a stately but rather formal professional intercourse, a picturesque ceremonial furbished with tags of scholastic learning, a certain dignity of custom, and the observance of loyalty to certain past ways. In a number of these features Oxford resembled its sister on "reverend" Camus; and Osler was deeply gratified to have as his opposite number Clifford Allbutt, a classical scholar as well as a close friend.

Canadian by birth and upbringing, his ties with the Empire formed a cherished background to his life. The annals of European Medicine were familiar and dear to

him, and that his position should link him with Linacre, Sydenham, and Harvey rose, I think, almost daily to his thought. Not that he lived in the past; rather he trod a stage whose scenery was much of it furnished from the past. The very buildings had their fascination for him. Once as I walked alongside him across the open space between the Camera, the Bodleian, and All Souls, he stopped and, looking round, said: "The finest architectural view in Europe."

Love of Rare Books

One of the happinesses he cultivated in Oxford was to serve as showman to parties of transatlantic visitors and to introduce them to his favourite glimpses of the University scene—a personally conducted tour, leading finally to lunch at his own house with Lady Osler at the table. The number of guests might be anything up to fifteen or sixteen, and the hostess had little notice of exactly how many there would be. But the babble of conversation was unceasing, and their host seemed able to address them each one intimately—Tom, Jack, Jim, or whatever familiarity dictated. One regular item of their entertainment, laid out for their inspection in a small well-windowed room opposite the "Study," would be some dozen or so choice printed books, each volume open at a selected place. These specimen volumes would include first-rate rarities—a fifteenth-century Aristotle from a Paris press, a Descartes' *Method*, etc.

His library was housed mainly in one large room with open shelves reaching to the ceiling and a couple of turntable bookcases, one of them completely filled with editions of his favourite among all books, Sir Thomas Browne's *Religio Medici*. When he resided at Oxford he was engaged in cataloguing his library on a novel plan—a *Bibliotheca prima*, etc. After Osler's death this catalogue was completed by Dr. William Francis, and issued at the Clarendon Press, at the charge of Lady Osler, in a fine folio volume. The books themselves were bequeathed by him to the McGill University library, Montreal. So far as I know he kept none of his books under lock and key, although he was well aware of the frailty besetting certain book-collectors and could relate instances within his own experience. In the Preface to his monumental catalogue he gives some anecdotes of his own adventures in pursuit of specially desirable volumes. His book-collecting seemed to be a "catching complaint," for I think we may suppose it was started in Harvey Cushing—and in others—by Osler himself. A well-known bookseller in London used to say that he attributed to Osler's influence no small share in the increased antiquarian interest taken in early printed books on both sides of the Atlantic. Osler was certainly a most intriguing devotee of the fashion.

A Special Interest

One of the adjuncts of the Oxford chair exerted quite a special appeal on Osler. In virtue of his tenure of the chair he was Master of an ancient almshouse some ten miles out of Oxford, a picturesque low-roofed cloistered building dating from the foundation of the charity, and enclosing perhaps half an acre of plotted garden. The apartments of the old pensioners themselves faced inwards towards this court. The whole stood in a small village which in itself was old-world, rural, and intersected by little running streams or "freshets" full of watercress grown for the London market. Lady Osler made herself unobtrusively a fairy godmother to these aged dependants. Osler as Master had a couple of rooms under the common roof. I happened to be present when he noticed a sort of strong-box in his bedchamber there. The key, wher inquired for, was not to be found, and Osler, thoroughly intrigued, wired to Chubb's, of London, for an expert to pick the ancient lock. The expert when he came looked at the chest, then, taking a small wooden mallet from his travelling-bag, tapped the sides of the lid and almos at once lifted it. "This chest has not been locked thes many years," he said. The box contained deeds, many of them on vellum with seals attached, each seal in its littl case fixed to the ribbon belonging to the document. Osle was enchanted. All the way home he could speak o nothing else.

As Consultant

I fancy that his opinion was considerably sought as consultant during his Oxford years. I was present one when it was—unofficially—appealed to. It interested m to see his manner change at once. It became gravely pro fessional. His voice assumed a deeper tone, his forel frowned slightly; his lips tightened, his bearing becam dramatic and oracular—kindly always, but now dispensin kindness oracularly. His position in Oxford was such th he allowed himself to call on sick people independently invitation from their doctor. William Macdougall, th psychologist, was then in Oxford, and I knew him well. H told me the following. His youngest child, a little ma of 7, was fatally ill. One afternoon Osler called, and afte talking with Macdougall they both went upstairs to th child's room. Outside her room Osler suddenly stopped and tapped at the bottom of the door. Then, opening he stole across to the child's bed with little steps and kne bent to dwarf himself as much as possible, his coat-flap nearly touching the floor, his face on a level with th child's in bed. The child gazed wonderingly at him "Mary," Osler said, assuming a small bird-like voice, I am come to tell you a secret—a nice secret. You are goi soon to leave us. You will be leaving on a journey, to beautiful place, a wonderful place where you will be ver very happy. And all your friends will soon be comin there to join you. I can't stay longer now; I must go off. Good-bye, Mary; God bless you." And he kisse the child gently on the forehead. Then he withdrew he had come, the little girl watching him wondering with a long smile.

Osler's Son

Osler himself had one child, a son, about to enter Chri Church when the first world war broke out. Revere share some of the tastes of his father, and the pair were several ways almost like schoolfellows together. Th world war had been expected by many, but not by Osler When it came Osler's parental anxiety was pathetic t see. After a year of delay his son was called up fo military training; then, rather more than a year later still for service abroad. Almost at once (1917) tragedy hap pened—a chance shell from a far range. The surgeon nearest at hand was the old family friend Harvey Cushing but there was nothing to be done. To Osler the news was overwhelming. He strove on bravely but hopelessly. Th laboratory attendants hearing his step declared it was no longer as it had been. As the year 1919 drew near its close, wintry weather caught him in a hired car far from home in a lonely place towards nightfall, and the car broke down. He and the chauffeur had to pass the night there, and he was chilled through. A day later he arrived home looking ill. He went to bed; bronchopneumonia set in. After some weeks he died, exhausted.

At the funeral service the Cathedral was filled to over flowing—friends attended not only from Oxford but from long distances.

I am not competent even to attempt any judgment of Osler's distinction as a clinician. He had of course a certain position as a man of letters. His literary style was rather obviously formed on his prime favourite, Browne of the *Religio*, without the redundant wealth of classical allusion. One conviction about Osler's influence on his time, of which I am quite sure and to which I would here bear witness, regards the remarkable camaraderie and personal affection which radiated from him. It stood for friendships which were lifelong ties. It was contagious. It propagated itself along his social contacts wherever he moved. His unlocked bookshelves were a part of it. In Baltimore, when he and Cushing occupied adjoining houses, doorways were cut through on each floor to facilitate communication between the households.

THE OSLER FAMILY

BY

W. W. FRANCIS, M.D.
Librarian, Osler Library, McGill University, Montreal

Osler's ancestors were seafarers of Falmouth, small shipowners, privateersmen, and merchants. His great-grandfather died of wounds in the West Indies; one great-uncle was killed in a sea fight, and another successfully fought off the Barbary pirates from a shipload of settlers he was taking to the Cape. His descendants are numerous in South Africa and Australia—some of them physicians, some cricketers, and a few both. Osler's great-grandmother, a sister of Samuel Drew, "the Cornish metaphysician," is suspected of having infused brains into the line, and it is certain that cheerfulness was irradiated by his grandmother, Mary Osler, better known to the end of her long life as Polly Paddy.

The statement in a recent biography of Sir Jonathan Hutchinson that he and Osler had common collaterals in Lincolnshire is a mistake: Lady Osler, not Sir William, was descended from the learned Anne Hutchinson, who in 1643 was massacred with all but one of her seventeen children near what is now New York.

Change in Bent

With the religious revival in the early nineteenth century the bent of the family changed. Of the five sons of Osler's grandfather, the eldest was a surgeon and an ardent churchman, and two became missionaries. Edward Osler (1798–1863), who attained the distinction of a notice in the *Dictionary of National Biography*, qualified M.R.C.S. at Guy's and St. Thomas's after an apprenticeship with a surgeon in Truro. His MS. eye-witness account of Cooper's famous ligation of the aorta is in the Wills Library. Becalmed on the way to London in 1816 in one of his father's packets, they were jeered one evening by a passing newfangled steamer, but had the satisfaction of overtaking it next morning and offering a tow! For seven years house-surgeon of the Swansea Infirmary, he afterwards practised at Bath and Truro. He is better known as a miscellaneous writer, author of *Church and King*, *The Life of Admiral Viscount Exmouth*, and poems; a hymn-writer ("O God unseen, yet ever near," is almost the sole survivor); and editor of the *Cornwall Gazette* for twenty years. Biological papers of his on marine animalcules were presented to the Royal Society and printed in the *Transactions*. All that I, his grandson, ever heard of his surgical practice is that he was delighted to be summoned one morning to a grand house in the country, and on arrival was told by a supercilious butler to wait in the hall till her ladyship should be ready. Not he! The house had a famous library, to which he found his own way. It was mid afternoon when he remembered what he had come for! His only descendants are in Canada, where his two daughters were a great help to Osler in his Montreal years.

Sir William's Parents

Featherstone Lake Osler (1805–95), the father of Sir William, was a venturesome lad who was sent to school inland to keep him from drowning: but at the age of 12 he was at sea and nearly lost his life in his first wreck. He then joined the Royal Navy and saw varied service in several ships, including the *Victory*, and rose to the rank of lieutenant. Having become something of a student, especially of mathematics, he entered St. Catherine's Hall, Cambridge, in 1833, with a view to taking orders. Thanks to an influential godfather, his prospects in the Church were particularly bright, but in 1836, in answer to a strong appeal, the Upper Canada Clergy Society was formed and he was persuaded that his duty lay there. The next year found him and his bride in what were then the wilds of Canada, forty miles north of Toronto. Undaunted by the incredible hardships of the first few years, they laboured here for two decades, teaching everything from theology to agriculture and sewing. He held services in twenty different places scattered over 2,000 square miles of country. At some distant gatherings he would announce the date of the next service six months or more hence, and the congregation would be there without, as he said, any further notice. One sees where W. O. got his punctuality! The parson's household—when he managed to get a house built—comprised at one time, besides his growing family, five young men whom he was training for the ministry. These included his youngest brother, Henry (1815–1902). A breakdown in health occasioned a visit home in 1841, and the most useful gift, besides money, which he brought back was many dozen pairs of spectacles for those of his flock with failing eyesight.

Osler's mother, Ellen Free Pickton (1806–1907), was a really remarkable woman, small in build and stature, but with tireless energy. Dark as her husband was fair, she was a Cornish "Black Celt," with beautiful features, enlivened by an unfailing wit and good humour, which more than matched her piety. Her influence was long remembered. Girls came from miles around to her Sunday school and to her Thursday afternoon class, which was meant to teach sewing but included everything. Usually thirty would arrive early in the morning and stay all day. Her greatest achievement, however, was bringing into the world and bringing up in the backwoods no fewer than nine children despite her late start: for she was 30 when she married in 1837. She lived to enjoy her hundredth birthday, but left it to her great-grandchildren to blow out the one hundred candles on it. Did it remind her of her first Sunday-school picnic, when she baked three barrels of flour into cakes and bread and fed seven hundred from twelve of her husband's nearest settlements?

Children of Distinction

Brought up by such parents under pioneering conditions in a country parsonage where helpfulness and self-reliance were the order of the day, no wonder that four of the six sons attained distinction. They were educated at an excellent grammar school in Barrie, sixteen miles from their home, and the elder three later studied law in Toronto. When William was 6 the family moved to Dundas, in a

much more advanced district where the amenities were greater and life less strenuous. Unfortunately, little is recorded of the children's younger days, except some of W. O.'s escapades, such as cutting off the tip of his sister's finger, "smoking out the old girl"—namely, the school's unpopular housekeeper—for which he spent a day in gaol and was fined a dollar and costs; or his earliest recollection, which he told so often that he came to believe he could remember how, in his second year, the day his younger sister was born, a calf with which he was tethered butted him into the pail of milk they were sharing and nearly drowned him. A visiting English cousin described him at 16 as "a light-hearted boy, but with many of the tastes and much of the dependableness of a man."

The eldest brother, Featherston (1838–1924), probably the most learned of the family, was thirty years on the bench and head of the commission revising the Statutes of Ontario. His three sons became distinguished lawyers. The non-medical majority of the family consider Britton, known as "B. B." (1839–1901), the most remarkable figure of them all. He was the greatest civil and criminal lawyer of Canada, the "thirteenth juryman." Some of his cases, notably his prosecution of the murderer Burchall, attracted attention in England, and it is a pity that his speeches were not collected and published. Like his medical brother, he had a thorough understanding of his fellow men, with personal magnetism, courtesy, and accessibility. The next lawyer brother, Edward (1842–1906), was early crippled with arthritis. The fourth brother, Sir Edmund, known as "E. B." (1845–1924), early went into business and became a leading financier, a director of the Canadian Pacific Railway, and a member of the Dominion parliament. That did not prevent his being a man of learning also. It was to his generosity that W. O., not four years his junior, owed his two years of postgraduate study and ready help in other financial crises. As for hospitality, at his summer place on Lake Simcoe, not far from his childhood home, I have seen fifty-six sit down to Sunday dinner. "He has the warmest heart and the most open hand of any man I know," wrote Sir William.

A year and a half ahead of W. O. came far from identical twins. The girl, a model of all the virtues, became the mother of nine of the best-looking children in Canada, while the boy became the nearest thing in the family to a dusky sheep—there was nothing black about him. His mother blamed herself for his shortcomings, as she was unable to manage both twins, and the boy was suckled by a squaw. No wonder he became a rolling stone! Whenever possible his adoring young brother used to take the blame and the punishment for Frank's peccadilloes. He ran away (800 miles!) to sea in his teens, was shanghaied, woke up on a whaler, and was missing for two years. His adventures, which included service as a *brancardier* in the Franco-Prussian War, would have been worth recording, but he was quite inarticulate, though a cheerful soul. With a devoted wife who kept the purse-strings tight and the bottle corked, he settled on a fruit farm. Their only son, a most promising young man, was killed, like W. O.'s, in the war of 1914–18. This was a new bond between the brothers, and on lugubrious occasions, such as Christmas, W. O. was not above slipping him a banknote, with disquieting results! The last I saw of the dear old fellow was in 1928 at Lady Osler's funeral. Returning from the Cathedral, we passed the end of St. Giles Street. The Fair was on; he heard the roundabouts, stopped the car, and disappeared more like an 8-year-old than an 81-year-old. He outlived them all, dying in 1932.

In 1937 there had been in America 225 descendants of the three Cornish brothers, all creditable citizens, and among them four physicians—none of the Osler name—including the lamented W. O. Abbott (1902–43), of Philadelphia, a gifted teacher (like his great-uncle) and the co-inventor of the life-saving Miller–Abbott tube.

OSLER: SOME PERSONAL RECOLLECTIONS

BY

CHARLES SINGER, M.D., D.Sc., D.Litt., F.R.C.P.

Emeritus Professor of History of Medicine, University of London

My first meeting with Osler was in the winter of 1904–5, when I took the M.B. at Oxford. I had made a small contribution to anatomical literature, illustrated by my own drawings, but was altogether astonished that he had read it and noticed my draughtsmanship. He found out from me that I was interested in Natural History and that I was shortly going to Malaya. A few days after I received from him some books on the fauna of that region. Later I learned to admire Osler's wonderful power of making every young man he met feel that he was in the presence of one who was taking a personal interest in him. Though this was doubtless the result of some conscious effort on Osler's part, it was certainly an effort that he loved to make, for it was a true and natural expression of the overflowing humanity that was part of him. Universal sympathy always seemed to me the essence of his greatness. His was especially a greatness of personality, and not of intellect, or of demonstrative skill, or of observational acumen, or of learning, or of literary power, though none could deny that he had all these things in good measure. I remained in some sort of relation with him for his last fifteen years, and for part of that time saw him almost daily. I am convinced that it was this universal sympathy that gave him that characteristic power to perceive and elicit the best in any companion.

What sort of figure did he seem to younger men, and why did he impress them so deeply? I can only tell how he appeared to me. He was a small, sallow, extremely dark, quickly moving man, of a lively and often puckish humour, very emotional withal and easily moved to tears, but when he was in earnest he had a grave deep voice which I learned to love. What always struck me most about his physical appearance was his lustrous, almost womanly eyes that seemed to suggest those of the Sistine Madonna. For, despite his gaiety, Osler always appeared to me as profoundly and essentially melancholy. I do not know, and there can now be none living who does know, of any deep sorrow that came to him in his earlier years, but to me he always appears as one who has passed through some tragedy to a life of human service, one who is always whispering to himself, "Down, thou climbing sorrow." It is a great and moving memory.

My contacts with Osler were naturally mainly of a literary kind and concerned especially older books and manuscripts. He was a true book-lover, to whom the very sight and touch of an ancient document brought a deep and subtle pleasure. His humanity, which seemed to me to be his leading characteristic, was especially brought out by the way in which he was constantly discerning the same essential humanness under the most different temporal, social, and personal conditions. Much of what was often regarded as his whimsicality was really a part of this search for the

man in many diversities. If he loved his books he loved the authors of them even more. His antiquarian interests were really a search for man in his diverse guises.

Thus he was a bibliographer and biographer rather than a historian in the proper sense. The literary reference-books that were most often in his hands were, I think, after the *Dictionary of Natural Biography*, Bayle and Thillaye's excellent *Biographie Médicale* and Ferguson's *Bibliotheca Chemica*, a work that contains far more than its title suggests. All are books which tell about people rather than about things. Osler was at his literary best either when he was musing on life and its vagaries or in such bio-bibliographical pamphlets as those on Servetus, on Linacre, or on Fracastorius. It is a great pity that he did not have time to treat in this way the sixteenth-century character whom he loved most of all, Conrad Gesner, for Osler bore some resemblance to Gesner in taste, in catholicity of interest, and even in personal appearance.

MY ASSOCIATION WITH OSLER

BY

LORD HORDER, G.C.V.O., M.D., F.R.C.P.

I first met Osler in England about 1900. He asked my support for his idea of an Association of Physicians, for the formation of which he was so largely responsible. Backed by his energy and influence, it was a great success from the word "Go."

We were next associated when the B.M.A. met at Leicester in 1905. Tooth opened a discussion on meningitis; I followed with an account of the lumbar puncture findings, and Osler, as a distinguished visitor, followed me. The sequence, though a logical one, was unfortunate for me—Osler's prestige was so high that the audience would barely hear me out and showed signs of impatience. "Turnips!" whispered Osler. "Your stuff is bed rock." In the years that followed I was to enjoy this kind of encouragement again and again—the encouragement of the 20-years-older man to his young colleague. I treasure a postcard which he wrote me when I was knighted in 1918: "I am glad it has come whilst the sun is on your face," it said.

In consultation Osler was profound in his knowledge of the "case," but not very impressive to the "friends." The diagnosis made, he tired a little in laying down a plan of treatment; so that it was not always easy to explain what had determined the choice of him as a final opinion.

In his last illness Osler paid me the signal compliment of asking me to go to Oxford to confer with his doctors. He was not only a very ill man, he was a man indifferent to life, so bludgeoned had he been by the loss of his beloved son. But he preserved towards us all that winning manner, and towards himself that equanimity, which we had always associated with him.

"When he came to die, Osler was, in a very real sense, the greatest physician of our time. He was one of Nature's chosen. Good looks, distinction, blithe benignant manners, a sunbright personality, radiant with kind feeling and good will toward his fellow men, an Apollonian poise, swiftness and surety of thought and speech, every gift of the gods was his; and to these were added careful training, unsurpassed clinical ability, the widest knowledge of his subject, the deepest interest in everything human, and a serene hold upon his fellows that was as a seal set upon them."—F. H. Garrison, *An Introduction to the History of Medicine*, 1929, page 631.

GRACE REVERE, LADY OSLER

BY

K. J. FRANKLIN, D.M., F.R.C.P.
Professor of Physiology, St. Bartholomew's Hospital Medical College

Some day someone will write a long-overdue essay on the ways in which great men in our profession, and in its allied sciences, have been aided in their achievement by the selfless devotion of their wives. Meanwhile it is supremely fitting that, in an issue commemorating Sir William Osler and his varied accomplishments, Lady Osler and her contribution should receive some special mention. For it is impossible to overrate what she did to stimulate "the great physician," to help him to make right decisions, to provide him with necessary recreation at home, to entertain their numerous friends while leaving him free for his work, and in countless other ways to be his ideal partner for twenty-seven eventful years.

"No. 13"

Mr. Arnold Muirhead, Dr. Harvey Cushing, and others have written of Grace Revere with far more intimate knowledge than I can claim, and my sole justifications for producing this account are the need already mentioned in the preceding paragraph, the present preoccupation of Mr. Muirhead with other matters, and the fact that I can perhaps be regarded as representing those many who, introduced to Lady Osler but with no special claims upon her, nevertheless received a warm welcome thenceforward at No. 13, Norham Gardens, found their hostess keenly interested in their relatively minor doings, and can look back on an inspiring friendship with a truly great lady to whom they remain for ever indebted.

As an ex-Service medical student at Oxford in 1919 I was privileged to have one short talk with Sir William. The next year an American theological student with whom I shared rooms, and who had brought with him an introduction to Lady Osler, asked if he might take me with him on his next visit to "The Open Arms" at No. 13. In consequence I became a regular caller there once or twice a term during the rest of my time in Oxford, met many of the Osler circle, and added considerably to my store of happy undergraduate memories. Oxford in those days was still a dream city, with a population only a quarter of its present figure, the surrounding country unspoiled, the Cherwell an enchanted stream, the beauty of the High as yet unsullied by the vast amount of traffic which now passes through it. At that time, too, to an extent which is now quite impossible, the friendly inhabitants of North Oxford dispensed hospitality each Sunday afternoon to undergraduates and others who called upon them, and thereby contributed greatly to the pleasure of our educative years. At Lady Osler's there were often thirty or more to tea, but each visitor was conscious of a personal welcome, and each came away stimulated and inspired by the kindness and interest which he or she had encountered.

The above is a pen-picture of the early nineteen-twenties, and for more information about the central figure in it, and particularly about the qualities which made her so ideal a wife to William Osler, we turn to the excellent biography by Mr. Muirhead.*

*Mr. Muirhead has most kindly given me permission to make such use as I will of his account.—K.J.F.

Ancestry and Early Life

Grace Revere was born in Boston on June 19, 1854, with French Huguenot ancestry on her paternal side and English on her maternal side; one of her great-grandfathers was the American patriot Paul Revere, and she displayed, as did he, "a strong will, positive opinions, and a delight in emergencies which called forth all" her "power and energies." From her parents, on the other hand, she inherited sympathy with and a desire to assist others, and these traits were *precociously developed* through the personal losses sustained by her family during the Civil War. Through her English-style schooling under Miss Foote in Boston she derived understanding of the people with whom in the future she was to have so much to do; throughout her life, too, she was an excellent letter-writer, and had an enviable memory for names. Finally, in so far as these general notes are concerned, we recall her love of flowers and her artistry in arranging them, also that she was as beautiful in her youth as she was handsome in her later years.

Her first husband, whom she married in 1876 and who was seventeen years her senior, was Dr. Samuel Weissel Gross, of Philadelphia. His father, the leading surgeon of the city, was a widower, and the young bride acted as hostess in his home as well as in her own. So she had early experience of large-scale entertaining, and from the beginning she proved herself a most efficient housekeeper. Apart from this not unimportant social side, she brought her strong will and enthusiasm to bear on her husband's professional career, and until his premature death from pneumonia in 1889 she fired him to greater efforts whenever his own ambition and spirits were flagging.

Her Marriage to Osler

William Osler, who had come from Montreal in 1884 to the Chair of Clinical Medicine in the University of Pennsylvania, had done so largely through Dr. Gross's persuasion. In 1889 he went from Philadelphia to Johns Hopkins and set to work on his great textbook; shortly after it was finished—i.e., in 1892—he married his friend's widow. They had reached an understanding earlier, but she had insisted, as she did on many subsequent occasions, that their personal inclinations should be made subservient to the greater claims of medicine, and she had brought Osler round to her point of view. Many more items could be extracted from the story of their joint life in America and in England up to the outbreak of war in 1914, but here I shall content myself with but three. The first is an example of her decisiveness, and it is given in the cable ("Don't procrastinate: accept at once") which she sent to him when he was in doubt, in 1904, if he should allow himself to be considered for the Regius Professorship at Oxford. The second shows her sense of humour, as well as the way in which she shielded Osler from non-professional chores which many husbands undertake for, or at least share with, their wives. When they were about to leave for England she had arranged all their household packing while he went off for three days with a handbag and thereafter met her at the steamer. This unequal division of labour produced the sly remark that "Willie's motto may well be *Aequanimitas*, because he always flies when things like this are going on." The third item recalls her remarkable personality, to which all who knew her pay affectionate tribute. Shortly before her husband was designated a Baronet in the Coronation Honours List she herself was presented at Court, and the girls who were presented with her said afterwards that "she looked as though she owned the Palace and was about to ask the King and Queen to spend a few days there!"

Her Courage in Bereavement

At the outbreak of war in 1914 she and her 18-year-old son, Edward Revere Osler, had just arrived in Canada on a visit to relatives and friends. They returned at once in the same boat, now painted black—Lady Osler to devote her seemingly endless energy to all kinds of war work, Revere soon to pass into the Army and eventually to die of wounds in August, 1917, in Belgium. The courage shown by his parents in carrying on after that appalling blow is a major item in their joint story, but it needs no redescription here. I will pass instead to 1919, in July of which year Osler received world-wide tribute on his seventieth birthday only to be stricken down with illness in September and to die in December. Lady Osler's feelings on this second blow can only be imagined, and she would have been tempted to leave Oxford but for two things. In the first place, she had to arrange for the completion and cataloguing of Osler's library and its transfer to Montreal; in the second, she found the tradition of No. 13 already so great that she could best help others by remaining there to receive old friends and to welcome new ones, to pass on something of Osler's spirit to those who could appreciate it, and to give to young people some of the love which Revere had not returned to enjoy.

How well she did all these things during the next eight years is well known; how valiant an effort it must have been for her to do them in her double bereavement can only be guessed. The main tasks, at all events, had been accomplished by the time that she herself died, at No. 13 and in the presence of her sister and of Dr. John Fulton, on Aug. 31, 1928. She remains in our grateful memories as "one who has loved and worked for the profession and the sweet influences of whose home have been felt by successive generations of students."

Under the Transfer of Functions (Food and Drugs) (Scotland) Order, 1949, certain functions exercised by the Secretary of State for Scotland will be taken over by or shared with the Minister of Food. The local authorities' duties of enforcement are not affected. The Ministry of Food will be responsible for those sections of the Food and Drugs (Adulteration) Act, 1928, which imposed restrictions on the mixing of colouring and other ingredients with foods and prohibit the sale of food not of the nature, substance, or quality demanded. The Ministry will also take over the Central Department's responsibilities under the Food and Drugs Acts relating to margarine, margarine-cheese, milk-blended butter, condensed milk, and dried milk. The Secretary of State will exercise jointly with the Minister of Food the general power to make regulations concerning the composition of food and the conditions under which it is imported, prepared, transported, or sold. The Secretary of State will be concerned mainly with hygiene and the Minister of Food with labelling and composition, but the Secretary of State will remain the central authority for the purposes of the Milk and Dairies Acts and the inspection of slaughter-houses and of meat derived from home-fed animals. The two Ministers will exercise jointly the power to make regulations governing the qualifications of public analysts. The Department of Health for Scotland will continue to supervise and give guidance to local authorities on these matters. The Secretary of State, acting through the Department of Health, will continue to be the central authority in respect of drugs coming within the scope of the Food and Drugs Acts and as regards the protection of the public from infected food.

TREATMENT OF 160 CASES OF ERYTHROBLASTOSIS FOETALIS WITH REPLACEMENT TRANSFUSION*

BY

J. J. van LOGHEM, M.D.

J. H. van BOLHUIS, M.D.

J. M. SOETERS, M.B.

AND

G. M. H. VEENEKLAAS, M.D.

From the Blood Grouping Department of the Central Laboratory of the Dutch Red Cross Blood Transfusion Service, Binnengasthuis, Amsterdam; Department of Paediatrics, University Hospital, Leiden; St. Ignatius Hospital, Breda; and Wilhelmina Children's University Hospital, Utrecht)

The discovery that Rh antagonism is a cause of erythroblastosis foetalis has revolutionized the treatment of this disease. Many authors consider early induction of labour to be a method of some importance in protecting the infant as much as possible against the attack of Rh antibodies, which pass the placenta mainly towards the end of pregnancy; when caesarean section is applied to prevent their penetration during labour. However, from several points of view this measure is open to discussion. Transfusions with washed Rh-negative cells or with Rh-negative whole blood have been widely applied with success. Maternal milk is often withheld because of the possibility of Rh antibodies being harmful in the first days of life through permeability of the intestinal tract. The application of vitamin K as a protection against haemorrhagic diathesis is still in use.

Owing to the studies of Wiener *et al.* (1947), Wallerstein (1947), Diamond (1947), and other workers a new method of treatment has been introduced. The principle of this method consists in replacing the Rh-positive infant's blood by Rh-negative blood of the homologous ABO group in order to eliminate the Rh-positive red cells, which will be rapidly haemolysed. At the same time Rh antibodies in the infant's circulation are washed out.

Although the different authors base their method of treatment on the same principle, the technique can be applied in various ways.

Wallerstein's method consists of infusion of blood into one of the greater veins, the blood being withdrawn with syringes out of the sinus sagittalis longitudinalis.

Wiener uses the saphenous vein for infusion of the blood and the radial artery for bleeding. It is very important to balance the rates of inflow and egress in order to prevent plethora by too rapid a transfusion, and to prevent shock from too rapid withdrawal of blood. In order to prevent clotting of blood the child is heparinized (Wiener and Wexler, 1946). Wiener, Wexler, and Shulman (1948) succeeded very well even with massive transfusions of 1,000 ml.

Diamond's method consists in introducing a plastic catheter into the umbilical vein. The exchange (or replacement) transfusion is performed by repeatedly replacing small quantities (20 ml.) of the infant's blood by citrated fresh donor's blood. He uses a closed system with the aid of three-way valves between catheter, syringe, and blood-transfusion ampoule.

In Holland exchange transfusion was started in January, 1947, as soon as the necessary information was obtained from Diamond and Wiener (van Loghem, 1948; van Loghem *et al.*, 1948). Exchange transfusion has been performed in 160 cases in two years by 43 physicians.* Nearly all the serological examinations were carried out in the Blood Grouping Department of the Central Laboratory of the Netherlands Red Cross.

Under the direction of the Working Committee for Rh Investigation courses of instruction were given; these greatly helped in acquainting physicians with simple methods of serological Rh-investigation and with the technique of exchange transfusion.

Diamond's method is very easy to perform, and was done even 40 hours after birth. Wiener's more complicated method does not offer any special advantage, except when the umbilical vein is obliterated, and even then it may be possible to use Diamond's method in one of the greater veins (vena femoralis). In only a few transfusions have we used Wiener's system.

Recently another method has been described which offers the possibility of performing the exchange transfusion through the umbilical vein a few days after birth, when the passage of the umbilical cord is obstructed. Pinkus (1948) described a new approach to the umbilical vein above the insertion of the umbilical cord.

Method of Treatment

Through lack of the plastic catheters recommended by Diamond one of us (Soeters, 1947) tried a rubber nelaton catheter which has now come into general use (No. 6—inner diameter 1 mm., outer diameter 2.6 mm. No. 8—inner diameter 1.5 mm., outer diameter 3.1 mm.—is also very useful). These catheters are very easy to insert into the umbilical vein. They are slightly modified—the end of the catheters being opened to facilitate the inflow of blood, or even cut off and well polished. One advantage they have over plastic catheters is that they are easy to sterilize by boiling and are very elastic. Furthermore, the end not being sharp, there is no danger of damaging the venous wall. A small glass tube is inserted between the rubber catheter and the adapter in order to control the inflow of blood and to prevent the inlet of bubbles of air. During the exchange of syringes the catheter is carefully closed by arterial forceps. One should be very careful in using the syringes. After every withdrawal and injection of blood they should be thoroughly washed in saline with heparin, and afterwards in pure saline. We use syringes of 20 ml. An assistant fills the syringes while the physician injects and withdraws the blood.

Heparinized blood is mostly employed for the exchange transfusion. "Heparine vitrum" (Brocades and Stheemann, Amsterdam), 20 mg. in 10 ml. of saline, is mixed with 500 ml. of donor blood of the homologous blood group. Heparinized blood should be administered within a few hours after taking, because heparin is apt to denaturate rather quickly. In general the infant is not heparinized. During the exchange transfusion the catheter is washed a few times with 1 or 2 ml. of a weak solution of heparin (2 mg. of heparin per ml.) in order to prevent clotting in the catheter. In our experience this is quite sufficient, although some prefer to heparinize the child by the injection of 10 mg. of heparin into the umbilical vein or intramuscularly before beginning the exchange transfusion.

If citrated blood is used, 90 ml. of 3.3% disodium citrate and 15% glucose is sufficient for 500 ml. of blood. Mollison

*Report of the Dutch Foundation for Blood Group Research.

*We are greatly indebted to all the physicians who have provided us with detailed clinical data of their exsanguinated babies and the necessary information about the histories of the pregnancies.

and Cutbush (1948) use the same quantity, 2.5 g. of disodium citrate and 3 g. of glucose, but dissolved in 50 ml. of distilled water, which has the advantage of preventing dilution of the blood so far as is possible. To increase the haemoglobin content of red cells of the donor blood Mollison eliminates about 50–100 ml. of the supernatant plasma citrate. By using citrated blood there is some risk of causing tetany by hypocalcaemia. About 5 ml. of a 10% solution of calcium gluconate is equivalent to the prescribed quantity of disodium citrate. To prevent tetany small quantities of calcium gluconate solution may be injected intravenously (about 1 ml. after every 100 ml. of citrated blood). It is also possible to administer calcium gluconate through the catheter, but previously the catheter should be washed carefully with saline in order to prevent clotting due to the presence of citrated blood.

As nearly all mothers of erythroblastotic children were submitted to an antenatal examination and were admitted to the hospital before delivery, it was possible to perform the exchange transfusion in nearly all cases immediately after birth, which has the advantage that the procedure goes very smoothly because of the free passage through the umbilical vein. It is also important from a therapeutic point of view to remove the Rh-positive blood and the Rh antibodies as soon as possible.

The infant is placed on an operation table in a well-heated room and held by a nurse. After disinfecting the abdominal skin with iodine the child is covered with sterile blankets and kept warm with electric cushions. Through the window (2 by 12 cm.) in the blanket the umbilical cord is brought outside. The operator, assistant, and nurse should take all the aseptic precautions necessary for an ordinary operation.

Before inserting the catheter the umbilical cord is cut off at a distance of about 1 or 2 cm. The cord is kept open with two forceps by an assistant, and the catheter is inserted into the great umbilical vein (6–8 cm.).

A stricture caused by fibrous tissue in the linea alba may obstruct the introduction of the catheter. It is always possible to pass this stricture—if necessary by dilatation by means of a sound. In any case it is advisable to cut off the cord very close to the skin to avoid unnecessary difficulty.

One of us (J.M.S.) studied the venous system of the newborn by means of *x*-ray photographs of cadavers after filling the venous system with thorotrast. In this way the catheter's route could be followed. It is possible to insert

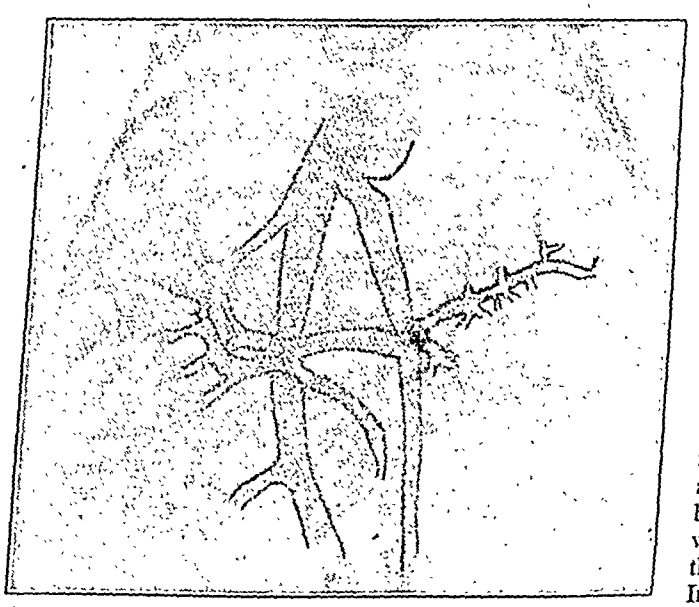

FIG. 1

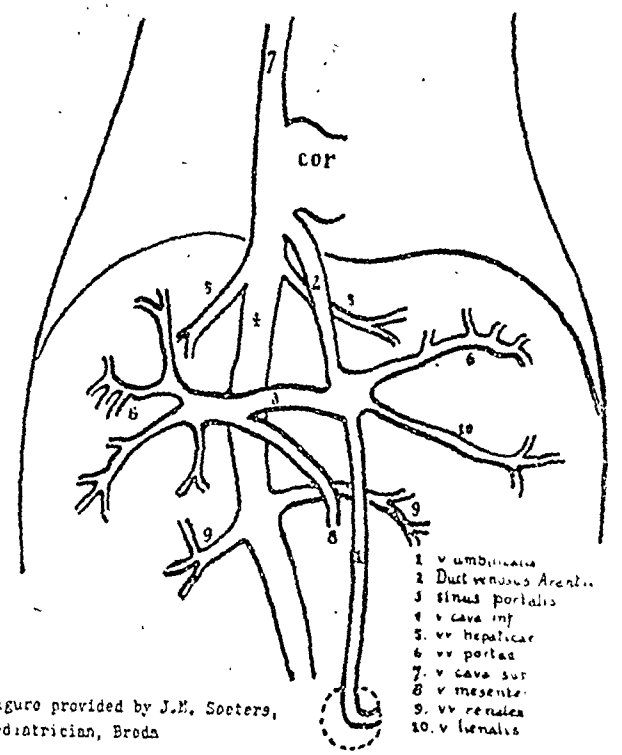

Figure provided by J.E. Soeters, pediatrician, Breda

FIG. 2

the catheter up to the vena *jugularis*. It passes umbilicalis, sinus portalis, ductus venosus Arant cava inferior, vena cava superior, and the vena (see Figs. 1 and 2). Sometimes it is difficult to h catheter into the ductus venosus *Arantii* because stricture of the distal part of the duct, when the is apt to turn off to the left or right side into the of the portal vein. When the catheter has been to a length of about 12–14 cm. it has reached th cava inferior. A stoppage at about 11 cm. that the catheter has entered the left or righ branches.

The withdrawal of blood from the vena cav proceeds very smoothly; in the sinus portalis it difficult. Most of us have found that it is not nec to insert the catheter up to 14 cm., but that the wi al and injection of blood is very easy to perfor after inserting the catheter into the umbilical vein for

The catheter is filled with saline and closed with terial forceps. When the catheter has reached its rig place a syringe filled with saline is fitted on to the catheter. The arterial forceps is now removed and a small amount of saline is injected very carefully. When this can be done smoothly, an attempt is made to withdraw the baby's blood. Sometimes it takes a few moments to find the right place in the umbilical vein for the injection and withdrawal of blood.

The quantities of aspirated and injected blood are carefully measured in order to prevent overdosage. In cases of severe anaemia a supplementary injection of blood (maximum 50 ml.) is given. The quantity needed for the replacement depends on the infant's blood volume. The amount of circulating blood is about one-tenth of the birth weight. In general an exchange transfusion is done with about one and a half times the blood volume. In this way at least 70–80% of the infant's blood is replaced. In nearly all cases of exchange transfusion the percentages of replaced blood were controlled by one of us (J.J.v.L.)

Methods Used

(*a*) The best method for calculating the percentages of replaced blood is that of Ashby, modified by Mollison (1947). To 1 ml. of a red-cell suspension in saline an equal amount of a very powerful anti-Rh (anti-D) agglutinating serum is added. After an incubation period of one hour the tubes are centrifuged for one minute; the tube is then gently shaken and stood for a few seconds to allow sedimentation of the large clumps to start, and a drop of fluid from the column is examined for the content of non-agglutinating cells. By means of a control of the same red-cell suspension with an equal amount of saline instead of anti-Rh serum the percentages of Rh-positive and Rh-negative cells are calculated. Before this examination the infant's red cells have to be eluted thoroughly, as they are coated with incomplete antibodies, which sometimes prevent strong agglutination. The non-agglutinating cells in both tubes are counted in a counting chamber. In the control tube there are no agglutinating cells; in the other one there are a number, depending on the presence of Rh-negative cells, as nearly all the Rh-positive cells are clumped by the anti-Rh serum.

(*b*) It is also possible to obtain a rather rough impression of the replacement of blood by determining the titres of iso-agglutinins α and/or β. This is done in the following way.

The titres of α and β agglutinins in the donor's blood are carefully determined. In the blood of newborn infants these iso-agglutinins are usually absent or very weak. By comparing the increasing titres of the above-mentioned iso-agglutinins in the succeeding fractions during and after the exchange transfusion with the titre of iso-agglutinins in the blood of the donor it is possible to find how much of the baby's blood is replaced by that of the donor. If the exchange transfusion has been done correctly and about one and a half volumes of the baby's blood used for the exchange transfusion, the titre of the last fraction of the baby's blood will generally be a little lower than the titre of the donor's blood.

The Rh factor and Coombs's test are controlled during the replacement and are found to become negative.

The percentage of replaced blood (method of Mollison) corresponds well with the mathematical formula given by Wiener, Wexler, and Shulman (1948). When the exchange transfusion has been completed 20,000 units of penicillin are injected and the catheter is withdrawn. The umbilical vein is ligated and the cord sutured with catgut.

Indications for Exchange Transfusion

The following factors are considered to be indications for this therapy.

It is very important to have the previous history of affected children. The death of previous children *in utero* during the last months of pregnancy certainly calls for early induction of labour, but not before the eighth month of pregnancy, because prematurity adversely influences the clinical course. Clinical manifestations, such as anaemia, jaundice, and oedema, are of great help in arriving at a decision. In the same way oedema of the umbilical cord and hydropic placenta are also important. A pale placenta weighing more than one-sixth of the birthweight must be regarded as a significant sign.

Sometimes it is very difficult to know whether an exchange transfusion is necessary. Serological investigations are often of great help (high titre of Rh antibodies of the incomplete form, homozygous genotype of the father). Occasionally there is a definite increase in the titre of Rh antibodies during pregnancy, but there may even be a fall in titre during the end of pregnancy. In general the control of the titre of Rh antibodies does not in itself give sufficient indication for exchange transfusion.

Sometimes the condition of the newborn may show a rather sudden and unfavourable change, so that even when the children seem to be in good condition it is necessary to apply exchange transfusion if the history of previous children is bad and the Rh factor and direct Coombs's test are positive.

Haematological examinations are of great value, especially when the infant shows no clinical symptoms shortly after birth. The findings may include hyperchromic anaemia, mild or strong leucocytosis with immature forms, erythroblastaemia, and hyperbilirubinaemia.

Mollison and Cutbush (1948) report that haemolytic disease was very mild in all infants whose cord-blood haemoglobin was above 15 g. per 100 ml. and cord-bilirubin concentration below 3 mg. per 100 ml., and that a stormy or fatal course would be likely in infants whose cord blood showed anaemia or a bilirubin value of over 4 mg. per 100 ml.

We observed a few cases in which the blood showed little abnormality shortly after birth and the bilirubin content was not increased in the cord blood, but kernicterus developed a few days after birth and the children died. We are inclined to believe that, apart from the haematological investigations, the other facts are of considerable importance.

The cord blood is used directly after birth for the necessary investigations preceding the exchange transfusion (direct Coombs's test, blood-group determination ABO and Rh, blood counts, blood smear, and bilirubin content).

The results of exchange transfusion are very favourable in cases of severe jaundice with anaemia, but it is difficult to decide whether it reduces the frequency of kernicterus.

The clinical symptoms gave the impression that haemolytic disease of the newborn is not merely restricted to the action of Rh antibodies on the red cells, but that liver, placenta, and other tissues also contain Rh antigen. The first investigations to establish the presence of Rh antigens in different tissues were done by Boorman and Dodd (1943). One of us has made a detailed study of this subject (van Bolhuis, 1948). The placenta of Rh-positive infants suffering from haemolytic disease of the newborn caused by Rh incompatibility nearly always had an inhibiting effect on Rh agglutinins. This influence was demonstrated in 27 out of 31 placentas.

Diseased parts of other organs, especially the basal ganglia of the brain in cases of kernicterus and the diseased liver in cases of icterus gravis, also have an inhibiting effect on Rh antibodies. On the other hand, suspensions of apparently normal organs do not absorb Rh agglutinins in any great quantity. It seems reasonable, therefore, to accept the view that kernicterus is due to the direct action of Rh antibodies on the brain, especially the basal ganglia, and that damage to the liver may be the result of Rh antibodies reacting with Rh antigen present in liver tissue.

Not until the diagnosis was firmly established on clinical and serological findings and the indication was clear was exchange transfusion performed.

Cerebral haemorrhage and congenital heart disease are, of course, contraindications to exchange transfusion.

Most cases were caused by D–d antagonism (replacement with cde/cde blood), one by C^W–C (cde/cde blood), one by c–C (replacement with CDe/CDe blood), one by B–O, and two by A–O antagonism.

Results of Exchange Transfusion

From Jan. 1, 1947, to Jan. 1, 1949, 160 newborn babies were treated with exchange transfusion*: 36 of them died—

*It is impossible to mention in detail here all the clinical and serological results of this material.

i.e., a mortality rate of 22.5%. The following were the causes of death.

Technical Failures.—Air embolism:—In one case the catheter was not closed during the exchange of syringes and caused aspiration of air. *Blood of the wrong group*:—Four children were treated with Rh-positive blood; two of them died shortly after the transfusion. It may be that Rh-positive blood was the cause of death, although the two other children had a normal clinical course. One case of A–O antagonism was treated with A rr blood: this child also died shortly after the operation. *Infection*:—One child died from sepsis. An abscess was found in the ductus Arantii. There were thrombosis of the portal vessels and multiple lung abscesses.

Possible Influence of Heparin.—In five children death was caused by: adrenal bleeding, 1; cerebral bleeding, 2; lung and cerebral bleeding, and bleeding in other visceral tissues, 1; and bleeding in all visceral tissues plus kernicterus, 1. It is not quite certain that heparin was the cause of death, but it may have had an influence on the haemorrhagic diathesis. Jorpes *et al.* (1939) proved that protamine sulphate synthesized in a special way is a harmless antidote against heparin. It is probable that it will be the medicament of the future to inactivate the action of this anticoagulant.

Treatment too Late.—One child was treated on the fifth day after birth. It already showed symptoms of kernicterus.

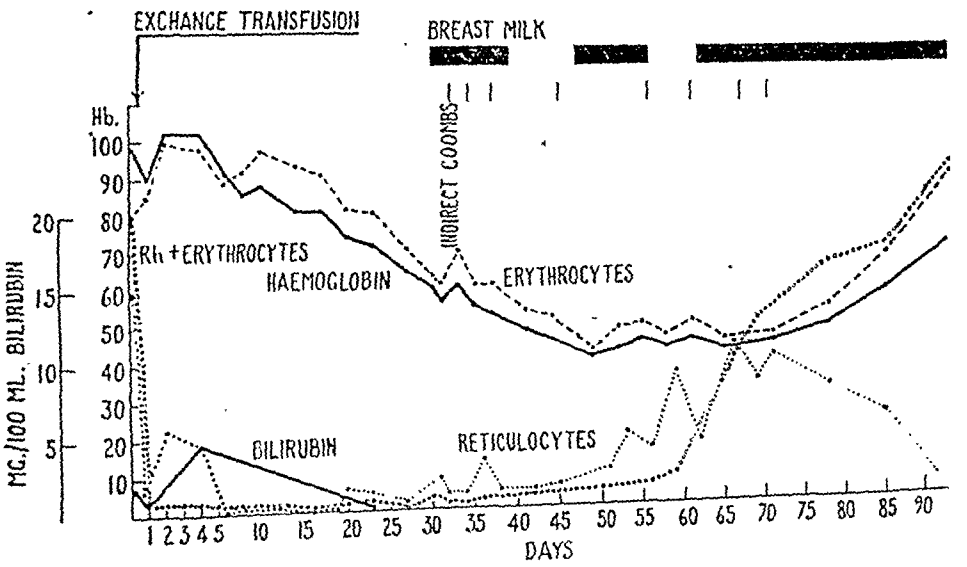
Treatment of Too-Premature Children.—Once exchange transfusion was applied to a baby 7½ months old. It is well known that prematurity has a bad influence on the diseased child.

Very Severe Cases of Haemolytic Disease of the Newborn.—Four exchange transfusions were applied to infants with hydrops foetalis, three of whom died. The child which survived was a milder case, with only oedema of the umbilical cord, hands, and feet, though it also had hepatosplenomegaly and a severe haemolytic anaemia (1,200,000 erythrocytes).

In the following cases there was nothing to suggest any relation to technical failures or other faults:

Eight children died with symptoms of kernicterus. One child died with cerebral symptoms (? kernicterus). Four children died from secondary infections about three to four weeks after birth—otitis plus gastritis, 1; [illegible] 2; scarlet fever or streptococcal sepsis, 1. S[illegible] shortly after birth without the cause of death being known. One child died from rupture of spleen (the preceding child also died from spleen rupture, although untreated). In 36 children the treatment was unsuccessful.

In order to arrive at the results of the therapy it seems reasonable to exclude the following cases in determining the mortality rate:



One case of air embolism; one case treated five days after birth, when symptoms of kernicterus were manifest; one case of sepsis; four cases of secondary infection, death occurring three weeks after birth; one case of spleen rupture.

By excluding these cases the mortality rate is reduced from 22.5 to 17.5%.

It is difficult to determine in what way the other above mentioned factors such as heparin, Rh-positive blood, and symptoms of hydrops foetalis have had a direct influence on the lethal course.

We have received information concerning the subsequent clinical course of 135 patients treated with exchange transfusion. In five cases there were sequelae of brain damage. In a great number of cases a hypochromic anaemia occurred up to three to nine weeks after birth, in one case even combined with a fresh attack of jaundice. In a few cases it was necessary to give supplementary transfusions with Rh-negative blood.

One of us (G.M.H.V.) made a detailed haematological study of his exsanguinated babies. Haemoglobin content and erythrocytes decreased in nearly all infants. In a few of them who could be followed up for a period of three months a severe anaemia with a haemoglobin content of 6.4–8 g.% (40–50%) developed in three to nine weeks. In most cases the red cell count and haemoglobin content increased spontaneously. The following facts were noticed, as shown in the accompanying Chart.

The decline in haemoglobin content and number of erythrocytes correlates with the physiological decay of the transfused Rh-negative erythrocytes. After three months these cells have nearly all vanished, and the infant's own Rh-positive erythrocytes have replaced them. It is remarkable that the bone marrow does not deliver Rh-positive cells sooner, for the total number of red cells is decreased gradually. The nucleated red cells disappear in a couple of days. The bilirubin content increases in general after the exchange transfusion. Although the liver-cell damage and the obstruction of the bile ducts will in most cases contribute to the jaundice after exchange transfusion, the increase of bilirubin may be caused by the total destruction of the remaining 20% Rh-positive erythrocytes.

In order to determine whether the mortality rate of icterus gravis was reduced significantly by this therapy we compared in the same families the percentage mortality of icterus gravis cases not treated with exchange transfusion with that of the newborn infants who were treated.

In examining the obstetrical histories of 88 families, out of the same group of 160, with 465 pregnancies we found the results given in the following Table. It will be seen that the mortality rate of icterus gravis is 73.7%, and including mild cases 63.5%. After treatment with exchange transfusion it decreased to 22.5%.

Before exchange transfusion came into practice the death rate had already decreased by application of partus arte praematurus, plasma transfusions, and Rh-negative whole blood or packed red cells (Parsons, 1947).

It is impossible for us to compare the mortality rate of icterus gravis treated by simple blood transfusions with

Table showing Comparison between Newborn Infants Treated with Exchange Transfusion and Cases of Icterus Gravis not so Treated

No. of Families	No. of Pregnancies	Normal Children	Mild Cases of E.F. (Haemol. Anaemia and Mild Jaundice)	Icterus Gravis		Stillbirth (5th to 9th Month)	Abortion
				Alive	Died		
88	465	192 (41%)	25 (5·3%)	41	115	57 (12·2%)	38 (8·1%)
				156 (33·5%)			

Mortality rate of icterus gravis, 73·7%.
Mortality rate of icterus gravis, mild cases included, 63·5%.
Mortality rate of 160 cases of icterus gravis treated with exchange transfusion 22·5%.

that of cases treated by exchange transfusion, for we have not sufficient personal experience of the latter.

It is beyond doubt that the prognosis in icterus gravis of the newborn has improved considerably owing to the treatment with exchange transfusion, whether preceded or not by partus arte praematurus.

Summary

After a short introduction the method of exchange transfusion applied to 160 newborn infants suffering from haemolytic disease is described.

The indications for the application of exchange transfusion are discussed.

The mortality rate of 160 babies treated by this method was 22.5%.

In order to determine whether the mortality of icterus gravis was reduced by this therapy, the results of treatment with exchange transfusion were compared with those in icterus gravis of children not so treated. Although we have no data on the results of treatment with simple transfusion of Rh-negative blood, the difference (63.5 to 22.5%) seems to indicate that the prognosis of the newborn suffering from icterus gravis has improved considerably by the application of exchange transfusion.

We wish to express our gratitude to Dr. R. R. Race for all his kind help and much useful advice.

We are greatly indebted to Miss M. v. d. Hart and Miss A. Paulussen for their skilful help in serological investigations and statistical analysis.

The Minister of Health intends to dispose of all hospital land and premises other than those which are being used or are likely to be needed for the hospital service. Hospital management committees have been asked to consider what property is suitable for disposal. The Minister will agree to the retention of endowed property only where there is a clear need for it—for example, when in the hospital board's opinion it should be reserved for future development. If the development and disposal of hospital property near a hospital is likely to injure the amenities of the hospital, the Ministry's attention should be drawn to the risk, so that it can consider including restrictive covenants in the conveyance of the property. In some cases boards may wish to make a case for the retention of such property.

A CASE OF ANAMNESTIC REACTION WITH Rh AGGLUTININS

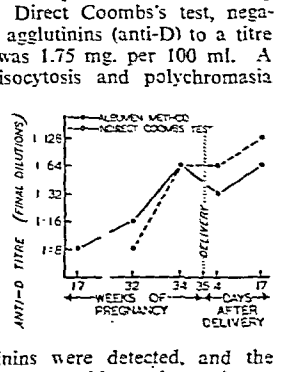
BY

D. A. OSBORN, M.B., B.S.

Assistant Clinical Pathologist, Guy's Hospital

Since the recognition of the importance of Rh agglutinins in relation to pregnancy and haemolytic disease of the newborn the interpretation of the serological findings has become a rather complex problem. The discovery of Rh agglutinins during the antenatal period does not necessarily foreshadow damage to the foetus, as it may represent a "carry-over" from the previous pregnancy. Of much greater significance is the demonstration of a rising titre, which is generally accepted as evidence of specific antigenic stimulation by the Rhesus-incompatible cells from the foetus. The importance of this assumption hardly needs to be emphasized, since on it may depend the decision to induce premature labour.

The following case is recorded because of its rarity and to draw attention to a possible alternative interpretation of the serological findings in pregnancy.



Case Report

The patient, a woman aged 34, had been married twice. By the first marriage she had a normal male child. Eight years later, in December, 1945, she was delivered of a normal male infant (by the second marriage). In December, 1947, she gave birth to a male child which was normal at birth but became jaundiced on the second day and died on the sixth day, deeply jaundiced and exhibiting kernicterus.

At this time the mother was found to be Rh-negative and her husband was thought to be homozygous positive. The infant was found to be R_2r (cDE/cde). The mother's serum contained albumin agglutinins to a serum dilution of 1:16.

In 1948 she became pregnant again and attended the antenatal clinic of this hospital. At the 17th week of pregnancy her serum was found to contain albumin agglutinins (anti-D) to a titre of 1:8. Examination of the patient's cells showed her to be group A_1,N,rr. At the 32nd week the titre was estimated to be 1:16, and two weeks later it had risen to 1:64. Taking into account the past history and the rising titre of antibodies, it was decided to induce labour in the 35th week. A normal female infant was subsequently delivered and has since made good and uneventful progress.

Examination of the cord blood yielded the following information: Group A_1,MN,rr. Direct Coombs's test, negative. Serum contained albumin agglutinins (anti-D) to a titre of 1:32. The serum bilirubin was 1.75 mg. per 100 ml. A blood film showed marked anisocytosis and polychromasia and a number of nucleated red cells (late forms)—approximately 9 per 100 white cells. A haemoglobin estimation performed on capillary blood was 18.9 g. per 100 ml. The picture was consistent with the degree of prematurity.

Examination of the mother's serum four and 17 days after delivery gave titres of 1 : 32 and 1 : 64 respectively—in albumin (see Chart). No saline agglutinins were detected, and the indirect Coombs's test gave fairly comparable results as shown. No anti-M could be detected in the mother's serum. Examination of the father's blood showed him to be group A_1, R_2r.

Discussion

The delivery of a D-negative infant came as a surprise in the face of the alleged genotype of the father, but, this

having been satisfactorily explained, interest was focused on the rising anti-D titre. After repetition of the tests it was concluded that the rise was more than could be accounted for by technical error.

This would therefore appear to be an example of an anamnestic reaction. While others have apparently observed the phenomenon in connexion with Rh agglutinins, only one case has been recorded so far (Davidsohn, 1948). The latter described the case of a woman who had an affected child by a homozygous husband and three years later became pregnant by a D-negative artificial insemination donor. A normal D-negative child was subsequently born, but a marked rise in agglutinins was observed about the sixth month of pregnancy. In the bacteriological field, in which anamnestic reactions have previously been studied, attempts to reproduce the phenomenon experimentally have not given consistent results. However, it has been pointed out (Topley and Wilson, 1936) that where an appreciable rise did occur in response to the introduction of a second antigen, the latter bore some relation to the primary antigen.

Our knowledge of the chemistry of the blood-group antigens has been considerably increased in respect of the ABO system (Morgan, 1947), but is very much more scanty so far as the other antigens are concerned. However, one might reasonably look in this direction for a source of antigenic stimulation in anamnestic reactions, since they apparently occur amongst the ABO substances (Davidsohn, 1948).

In Davidsohn's case there was no ABO incompatibility between the mother and infant, and the MN grouping of the mother was not known. In the present case the only foreign antigen is the M derived from the MN cells of the infant. This is known to be a weak antigen in man, and anti-M has been detected in human serum (Paterson, Race, and Taylor, 1942). Whether M has anything in common with the Rh antigens is a matter for speculation, but the failure to detect anti-M in the mother's serum would seem to rule out any possibility of M being responsible for the rise in anti-D titre in this case.

The problem remains, therefore, in both its clinical and its more academic aspects. From a practical point of view a rising anti-D titre will result in one of three possibilities: (1) an affected D-positive infant, (2) an unaffected D-positive infant, or (3) an unaffected D-negative infant (anamnestic reaction). In coming to a decision the obstetrician will undoubtedly set against induction the second and third possibilities. There are grounds for hoping that in the not too distant future an explanation of why a positive infant may escape can be turned to practical advantage, and in order that the third possibility may be put into its proper perspective it is obviously relevant to know how often an anamnestic reaction may occur.

I am indebted to Dr. A. E. Mourant, of the Lister Institute, for his advice and help in genotyping and MN grouping; to Dr. J. Murray, of Queen Charlotte's Hospital, for kindly supplying details of previous investigations; to Mr. G. F. Gibberd and Dr. F. A. Knott for permission to publish this case; and to various members of the laboratory staff for their assistance.

CARCINOMA OF THE BREAST IN CASTRATED WOMEN

BY

M. DARGENT, M.D.

Surgeon, Centre Anticancéreux, Lyons

Although it well known that carcinoma of the breast m occur after the natural menopause, and although it is a established that women of 60 and 70 may suffer from ac carcinomatous mastitis, carcinoma of the breast occurr after castration, performed either by irradiation or by s gery, is a less familiar condition. At a time when castration is being suggested by many workers as a sound adjuvant in the treatment of cancer it is useful to recall the following facts.

Anatomical and Clinical Data

1. *Frequency.*—In 2,000 cases of carcinoma of the breast I have found 32 (1.6%) occurring in castrated women (statistics from the Centre Anticancéreux, Lyons). This figure is higher than that of carcinoma occurring during pregnancy (21, or 1.05%) or in men (16, or 0.8%).

Summary of Results

2. *Age of Onset.*—The Table shows the age at castration and the age at onset of carcinoma, the limits of which are 35 to 85 years. There are seven cases between 50 and 55 years and nine between 60 and 65. These are the same as the highest figures for carcinoma of the breast in non-castrated subjects, but with a particular predilection for the 55 to 65 age group.

3. *Interval Between Castration and the Onset of Carcinoma.*—This ranged from two months to 24 years. In nine cases only was it less than five years, and it must be admitted that the cancer might have already been established at the time of castration. In 23 cases the interval was over five years.

4. *Means of Castration.*—These are shown in the Table. In seven cases castration was performed by irradiation (three by radium and four by *x* rays) and was followed by amenorrhoea when done before the menopause.

5. *Indications for Castration.*—In 19 cases castration was performed for fibroids or metropathia haemorrhagica. In 16 of these cases the procedure was carried out before the age of 48. There was one case of bilateral pyosalpinx (age 42), one case of prolapse (age 60—vaginal hysterectomy performed), two cases of carcinoma of the cervix, and one case of recurrent tumour of the ovary that was operated upon when the patient was aged 32 and 43. (This appeared as a solid tumour, the exact nature of which it was impossible to determine.) Eight cases were castrated for miscellaneous reasons.

6. *Influence of Age at Castration on the Interval before the Appearance of Carcinoma.*—It is impossible to correlate the age at castration with the interval before the onset of carcinoma. One can only observe that when castration is performed after the age of 50 the interval is often short (four cases out of eight). In 16 cases in which castration was performed during the menopause, between 40 and 50 years of age, the interval was usually long. In only two cases was it less than five years, and these two patients survived longer than five years.

7. *Types of Carcinoma.*—When first examined the patients presented carcinomas that could be classified as follows: grade 1, 9 cases; grade 2, 11 cases; grades 3 and 4, 9 cases; not precisely classified, 3 cases. Among the nine advanced types five had developed in less than six months. Only one had developed over a period of 10 years, after the age of 45; this patient had undergone castration by *x* rays at 38. No comment need be made concerning the morphological type or histological picture of these carcinomas. Only one was of the endocrine type.

8. *Mode of Development of Carcinomas.*—These carcinomas appeared to be particularly malignant. Of 32 patients one was not followed up, one survived for two years, two survived three years and now show evidence of recurrence, and four survived up to 10 years. Of the 24 patients who died of carcinoma, five survived five years after treatment. These were five women castrated at an early age (28 to 46). One (Case 1) had been operated upon two years after the appearance of the tumour. The condition recurred in the sixth to the ninth year after treatment, in the form of metastases in the lungs or widespread metastases in the vertebrae. On the other hand, seven patients out of 24 died in less than a year. Among these there were two with grade 1 carcinomas; both were castrated at the age of 32 and developed carcinoma at 35 and 53. The other five patients had grade 4 carcinoma which developed in less than six months and permitted only palliative treatment.

9. *Remarks on Case Histories.*—The effect of treatment must be taken into account in deciding the length of time during which the carcinomas developed. Apart from one case which was treated by a combination of surgery and irradiation, all the others (i.e., 23) that were suitable for radical treatment underwent Halsted's operation (with the exception of one patient with grade 1 carcinoma treated by local mastectomy). Four patients survived up to 10 years without recurrences among these 23 cases, giving one of the worst statistical results in surgery.

Some cases seem to merit special mention: (*a*) in two definite cases (carcinoma of the cervix) and in one probable case (recurrent tumour of the ovary) castration was indicated for malignant tumour of the genital tract; (*b*) in 19 cases out of 32 castration was performed for a fibroid or for hyperplasia of the uterus; (*c*) nine post-menopausal cases were retained in the series because many pathologists consider that even in these circumstances castration still has a favourable action. No conclusion can be drawn from my own observations.

In some cases there are circumstances that I consider to be especially unfavourable: one case had previously undergone a biopsy and had been treated with small doses of testosterone; after castration two cases developed goitres, one of which was toxic (these were removed); and in one case the woman's mental condition (neurasthenia) might have been responsible for the rapid development of the growth.

Comment

The study of these 32 cases demonstrates the relative rarity of carcinoma of the breast in castrated women. The figure arrived at (1.6%) agrees with the figure of 1.5% that Herrell (1937) has established. He included benign growths in his series, and showed that in a significant number of patients dying of non-cancerous conditions the frequency of antecedent castration was 15.4%. However, although rare in castrated women, cancer does occur. Interpretation of a limited number of results is always hazardous, and these observations are mainly set down for the purpose of recording the facts. It is, however, obvious that in this series the age of onset of carcinoma is relatively late, and that the number of patients above the age of 60 is significantly high. It is particularly interesting to note that when castration was performed between the age of 40 and 50—at the age when the amount of circulating folliculin is considered significant—carcinoma of the breast appeared in general late (in one case the interval reached 23 years), and in all cases the development of the carcinoma was rather slow, even in cases of early onset.

The large number of cases of highly malignant carcinoma, in young as well as old women, is surprising. It is on this point possible to invoke not only the earlier experimental work of Cori and Murray, referred to by all surgeons and radiotherapists supporting the principle of castration, but also the more precise results obtained by other workers. The liberation of the growth hormone of the pituitary after castration has been demonstrated by Sauerbruch and Knake (1937). The favourable action of the gonadotrophic hormone on the growth of tumours of an ovary, the follicular secretion of which has been neutralized by splenic implantation, has been demonstrated by Penchar and Biskind (1947). One should perhaps attribute to an action of this sort the rapid growth and early onset of mammary tumours after castration and the unfavourable influence of treatment of a goitre in two cases.

At the same time it is well known that the menopause, natural or artificial, does not always suppress the appearance of folliculin in the circulating blood, and endocrinologists have occasionally been able to discover the presence of significant levels. The discovery of hyperplasia or adenomas of the suprarenal by Wooley and Little (1945) in mice after castration at birth, and by Gardner (1942) in older animals, shows that probably it is this gland that ensures the secretion of folliculin after the castration, and in the experience of these authors the frequency of spontaneous carcinoma of the breast is not altered.

The age at which castration is performed is certainly highly important, and the appearance of extragenital folliculin capable of producing carcinoma of the mammary gland is probably not so rapid in castrated women in the stage of hyperfolliculinaemia. I present this simple theory to explain the relative benignancy of carcinoma of the

breast occurring after castration at the menopause. This hypothesis stands to be confirmed or disproved by frequent estimations of the amount of folliculin circulating during the years following castration. Since comment on these anatomical and clinical findings can be made only with the help of experimental data, it is important to measure here the extent of our ignorance in this field. It must be admitted that three factors are undoubtedly present at the time of the appearance and development of mammary carcinoma—the milk factor (Bittner's mammary tumour inciter), the genetic factor, and the hormonal factor. Of these the clinician knows only one. Wooley and Little, for example, have convincingly demonstrated that only certain strains of mice develop suprarenal hyperplasia after castration, and van Gulik, Korteweg, and Muilbock, of Amsterdam, have shown, following the work of Lacassagne (1939), that sensitivity to oestrone varies according to the strain studied.

Conclusions

Until clinicians possess as many data concerning their patients as experimental workers have concerning their mice, castration by surgery or irradiation will never become a therapeutic procedure the efficacy of which can be guaranteed. On the contrary, there are perhaps cases where sterilization will have harmful effects. From the practical point of view these and other observations on castration performed for carcinoma of the breast, either already treated or first seen in an advanced stage, leads to the following conclusions.

(*a*) When carcinoma of the breast begins after castration, or even in spite of castration, the prognosis should be regarded as bad unless castration was performed near the time of the menopause. Castration has therefore, above all, a value in prognosis.

(*b*) Routine castration after treatment of the carcinoma is not a guarantee against later manifestations of the malignant condition. The problem is evidently not the same as in the cases discussed here, since the mammary tumour has been removed or irradiated. The point is to assure prophylaxis against local recurrence or metastases to bones or viscera. The sensitivity of these different sites to the action of hormones is very variable, and there is no proof that all of them are likely to be influenced. We know, for example, that a recent case of surgical castration, done shortly after combined surgical and *x*-ray treatment for carcinoma of the breast in a woman of 34, was followed after three months by the appearance of extensive mediastinal and pulmonary metastases. Recently Rudler reported similar cases at the Académie de Chirurgie. The fact that castration, advocated more than fifty years ago by Shinzinger and Beatson, has never been generally accepted as a favourable measure is proof of its relative ineffectiveness. At present the results reported by Horsley (1947) are often quoted; he combined surgical castration with treatment of the primary lesion and obtained excellent results over a period of five years. I think that the restricted number of these cases and the follow-up period of five years render these results open to criticism, and observation of our own cases castrated at the menopause shows that the value of this procedure can be judged only after an interval of at least ten years.

(*c*) Castration by surgery or irradiation in advanced carcinoma of the breast has given us two good temporary results (of 3 to 13 months) in ten cases in which the castration was performed surgically; of 28 cases in which castration was performed by irradiation 14.39% showed some degree of remission. Cases of highly malignant carcinoma appearing in recently castrated young women make us consider the possibility of failure of castration in similar circumstances.

However, the immediate favourable effects, even on the day of operation, on the pain of vertebral metastases or on the lymphatic infiltration in the mammary region, lead one to envisage a special neuro-hormonal or vasomotor effect of castration rather than a long-lasting endocrine effect.

Surgical castration has, especially for me, an academic interest, since on four occasions out of ten I have found metastases from the mammary tumour in the ovary. In these four instances manifestations of malignancy were severe, and it is possible that the occurrence of metastases in the ovary brought about an exacerbation of the condition. This is a valuable pathological argument in favour of systematic castration after treatment of carcinoma of the breast, but the endocrine problem will not be settled on this single fact. Thus, although there still exist some reasons for castration in carcinoma of the breast, the prognosis of this condition after castration should remain very guarded.

Summary

Thirty-two cases of carcinoma of the breast have been observed after castration by surgery or irradiation. They represent 1.6% of a series of 2,000 cases. Only four of these patients have survived for ten years without recurrence. Many tumours grew rapidly despite castration. The longest interval before the appearance of carcinoma was in women castrated between the ages of 40 and 50. Some comments are made and conclusions reached on the value of castration in cancer of the breast.

CONGENITAL HEMIATROPHY ASSOCIATED WITH OTHER CONGENITAL DEFECTS

BY

W. L. CALNAN, M.B.

Minimal body asymmetry is very common in human development. Halperin (1931), in discussing normal asymmetry, states that the left side of the body is slightly larger than the right, particularly the cerebral hemisphere, skull, face, leg, and breast. When the inequality is such that it is noticed at or soon after birth it constitutes one of the rarest congenital abnormalities. The case reported here was associated with partial dental aplasis, cutaneous pigmentation, and talipes equinus.

Case Report

A girl aged 3 years 2 months was admitted to hospital in status epilepticus. Subsequent investigation showed that this was due to whooping-cough with bronchopneumonia. The status epilepticus was followed by a left-sided hemiplegi which cleared up completely after five days. The cerebr spinal fluid was normal. The Wassermann reaction w negative in mother and child.

The patient was a full-term second baby, and pregnancy an labour had been normal. The birth weight was 8 lb. (3.6 kg. The child was bottle-fed. The father developed shingles abou one week after the estimated date of conception. Bot parents are alive and well. There is no familial diseas or abnormality. At birth the child exhibited a vesicular erup tion on the left leg and on the dorsum of both hands. Thi condition lasted about four months and healed with scarring particularly on the left leg. The aetiology of this eruption i uncertain and may have been a bullous impetigo. Brow pigmentation of the skin was also present at birth, and it ha not altered in character or distribution.

When the child was 3 months old the mother noticed tha the left leg was shorter than the right. At 1 year the child walked with a painless limp, and the left leg was considered to

be weaker than the right. At 18 months she was seen by an orthopaedic surgeon, who found ¼-in. (0.95-cm.) shortening of the left leg. Recently the mother has had difficulty in obtaining a pair of shoes to fit both feet.

Examination

The child is thin and has a small face with a receding chin: height, 38 in. (96.5 cm.); weight, 26¾ lb. (12 kg.). She is right-handed. Although moderate in degree, the smallness of the left leg is immediately noticed. No scoliosis is seen clinically.

Head.—The left side seems flatter than the right, with narrowing of the left palpebral fissure. The ears and pupils are equal.

Skin.—There is an increased amount of hair present on the left arm and leg. Scalp hair is equally distributed. Atrophic hairless scars are present on the left arm and leg, corresponding to the site of the vesicular eruption in infancy. Melanotic linear pigmented areas are present over the anterior part of the trunk on the left side, extending for 2 in. (5 cm.) down the front of the thigh. This pigmentation is also present over the lateral wall of the thorax on the right side. It does not show a somatic segmental distribution. There are no cutaneous naevi, no evidence of sclerodermia, and no difference in sweating on the two sides.

Teeth.—Some deciduous and permanent teeth are absent. The distribution of the teeth is shown in Table I: of the deciduous teeth, the lateral incisor and first molar are absent from the right upper and lower jaws, and the upper lateral incisor is absent from the left side. No deciduous teeth are present in the left lower jaw. Of the permanent teeth, the lateral incisor, both pre-molars, and the second and third molars are absent from the right side in both upper and lower jaws, and in addition the canine is absent from the lower jaw. In the left upper jaw only the medial incisor and first molar are present. In the left lower jaw the only permanent unerupted tooth present resembles a canine in its radiological appearance, but it is well developed and calcified and shows some features of a lateral incisor.

TABLE I

e c a | a c d e	6 3 1 | 1 6
e c a |	6 1 | 2 (?)
Deciduous teeth	Permanent teeth (calcified unerupted)

Limbs.—The measurements are shown in Table II. The apparent smallness and shortening of the limbs on the left side are more striking than would be expected from the differences in measurements. All movements of the left leg are weaker than those of the right. A talipes equinus is present on the left side. Tilting of the pelvis when standing is seen clinically and radiologically. The difference in size of the long bones has been confirmed radiologically. Bone architecture is normal. The skull is normal radiologically. The bone age agrees with the chronological age, and no difference has been detected between the two sides.

TABLE II.—*Measurements of Limbs*

	Left	Right
Arms:		
Length of whole arm	28·5 cm.	29·0 cm.
Circumference of upper arm	16·5 cm.	16·2 cm.
Circumference of forearm	15·4 cm.	16·0 cm.
Length of third finger	5·8 cm.	6·0 cm.
Legs:		
Length of whole leg	46·0 cm.	47·6 cm.
Length of thigh	25·2 cm.	26·0 cm.
Length of lower leg	20·8 cm.	21·6 cm.
Circumference of thigh	29·0 cm.	30·1 cm.
Circumference of calf	18·7 cm.	19·8 cm.
Length of foot	14·5 cm.	15·0 cm.
Half circumference of trunk at level of umbilicus	26·5 cm.	28·0 cm.

The child's mental development is normal, and no abnormality was found in the central nervous system.

Discussion

In 1927 Kraus and Perkins reviewed the literature on hemiatrophy and collected 18 cases, of which only five were not associated with motor disorders such as hemiplegia and athetosis. They classified hemiatrophy into congenital, familial, and acquired types. The hemiatrophy may be partial or complete. The sex distribution is equal. Hemiatrophy more commonly affects the left side of the body, as opposed to hemihypertrophy, which is commoner on the right side. Later, Landauer (1939) was able to collect 22 cases of partial or complete hemiatrophy, mostly in America.

Mental defect and cutaneous abnormalities are common in cases of hemihypertrophy, but are rarely associated with hemiatrophy.

Only one of the cases of hemiatrophy reported by Kraus and Perkins showed cutaneous abnormality. The case reported by Masten (1936) showed cutaneous pigmentation and defects of the nails of the fingers and toes on the atrophied side. I have been unable to find a previous report of dental aplasia associated with unilateral atrophy. There is no familial history of dental or cutaneous abnormalities in the present case. The distribution of the teeth that are present shows some degree of symmetry.

The occurrence of transient hemiplegia affecting the left side following convulsions suggests an abnormality in the right cerebral hemisphere. Unfortunately it was not possible to carry out encephalography in this case. Ross (1941) found cerebral atrophy in cases of infantile hemiplegia. Penfield and Robertson (1943) examined cases of growth arrest and atrophy, and at operation found lesions (e.g., scarring) in the post-central gyrus of the contralateral cortex. The majority of their cases followed birth injury.

The aetiology of congenital hemiatrophy is still obscure. In the above case the history of shingles in the father shortly after the estimated date of conception of the child may be significant. It is possible that the male germ-plasm was affected by the virus, and this may have caused a defect in the resulting embryo. The asymmetry is probably apparent very early in foetal life. Phisalix (1888) found a 10-mm. human embryo which was asymmetrical. A case of congenital hemihypertrophy reported by Wakefield and Hines (1933) was associated with complete bilateral deafness. No further details are given.

Hemiatrophy is sometimes seen in chondrodysplasia (Ollier's disease), which is essentially a condition affecting one side of the body. Certain features of the case of hemiatrophy reported by Zondek (1945) were suggestive of Ollier's disease. There was no such evidence in my case.

Very few cases of congenital hemiatrophy without motor disorders are reported, but the condition is probably more common than a review of the literature suggests. There is a considerable variation in the degree of asymmetry in the cases, and also in the extent to which this asymmetry develops with growth of the patient. Both sides of the body may grow at the same rate or the difference may increase.

When the case is seen at an early age it is sometimes difficult to decide which is the abnormal side and whether the case is one of hemiatrophy or hemihypertrophy.

The association of dental aplasia predominantly on the left and the left-sided talipes equinus, muscle weakness, cutaneous pigmentation, and transient hemiplegia indicate that the left is the abnormal side in the present case.

Summary

A case of congenital hemiatrophy, associated with partial dental aplasia, cutaneous pigmentation, and talipes, is reported. A possible aetiological factor is mentioned.

I am indebted to Dr. M. E. Edmunds for permission to publish this case and for much helpful criticism and advice.

Medical Memoranda

A Case of Mepacrine Dermatitis

The following record is of interest because of several features not previously reported.

CASE REPORT

The patient was a private in the R.A.M.C., aged 36, with two years' service. He had previously been a plumber. In November, 1946, he had a generalized rash, most pronounced over the shoulders, loins, buttocks, internal aspects of forearms, and external aspects of legs. The axillae, palms, and soles were free. The rash consisted of deeply pigmented macules with petechiae, mainly in line with the ribs, and a keratotic follicular spiny element giving rise to a "nutmeg-grater" skin, chiefly present on the back. The nails were exfoliating and discoloured, and showed a pronounced heaping up—the so-called Beau line. The hair was thin on the scalp, and the outer third of the eyebrows had disappeared. There were some lichen-planus-like lesions of the mouth. No complaint of itching was made. The eruption had been present for three months.

The rash began on the waist after prickly heat at Singapore in March, 1946. It rapidly spread to the arms, legs, ears, feet, and forehead. The eyebrows and scalp hair began to fall at the same time, and the nails were also affected. The rash, originally red and irritating, soon developed into rough scaly spines, and had reached its present static state a month later. The patient had taken mepacrine for six months and had been in India for eight months before the eruption appeared. He had not noticed any irritation from khaki. The eruption had been diagnosed in Singapore as tropical lichenoid dermatitis.

He had suffered from backache and pains in the loins for the past six months, but had not had any other diseases. His mother has had a scaly rash of uncertain origin on her legs for many years. He complained of malaise and poor eyesight. On examination the B.P. was 120/65 mm. Hg. Nothing abnormal was found in the heart and lungs, abdomen, C.N.S., lymphatics, and upper respiratory tract. Urine: no albumin, sugar, bile; no deposit. Kahn test was negative. B.S.R., 8 mm. in one hour. A blood count showed: Hb, 118%; red cells, 5,500,500; C.I., 1.02; white cells, 6,600 (polymorphs 56%, lymphocytes 37%, monocytes 2%, eosinophils 5%). Platelets numbered 720,000 per c.mm. A radiograph revealed some calcified areas in the right base, but no evidence of active infiltration. The heart shadow was normal. The Hess tourniquet test was negative. Liver function shown by the Quick and Schlesinger tests was normal. A skin biopsy was done and the pathological report stated: "There is an increase in the stratum corneum. The granular layer appears more distinct than normal. There is considerable widening of the papillae, and the pars papillaris contains an excess of free and fixed cells and many melanophores." The mepacrine patch-test was negative. Soon after starting an oral test course of mepacrine the patient's lesions were aggravated. In addition he described a burning irritation of the hands and feet, which had not previously been affected. About this time he suddenly developed mental symptoms of a schizoid type, with confusion and excitement. On stopping the drug the mental condition rapidly returned to normal and the skin to its former state. Mental symptoms have been seen in cases of mepacrine intolerance (Gaskill and Fitz-Hugh, 1945; *British Medical Journal*, 1945; Duncan Shiers, 1946).

A variety of local applications and vitamin therapy appeared to have no specific effect, and this has been the general experience (Sulzberger and Baer, 1945). A year later the lesions were still present but showed considerable improvement, and the pigmentation was less intense.

COMMENT

There seems to be little doubt that in this case mepacrine was the cause of the dermatitis. The association of the skin condition with cerebral symptoms has not previously been described, and the nail dystrophy, which was such a pronounced feature, has not received much attention. Pigmentation (Lutterloh and Shallenberger, 1946) and loss of nails (Wilson, 1946) have been mentioned as occurring, while it is known by fluorescence under Wood's light that mepacrine is excreted in the nails (Kierland *et al.*, 1946). In the present case the Beau line of the nail corresponds in date with the first acute appearance of the eruption three months before. Growth of the nail has been normal since. Especially noteworthy is the long continuance of the eruption since cessation of the drug 18 months ago.

Acknowledgment is due to Dr. J. E. M. Wigley and to Dr. I. Muende for help in the investigation of this case, and to the War Office for permission to publish.

Rheumatic Pericarditis with Hyperpyrexia

It is stated by Miller in the *British Encyclopaedia of Medical Practice* that "rheumatic hyperpyrexia has now virtually disappeared. When it occurred it was almost always associated with acute pericarditis and was at one time usually fatal. It was always much commoner in adults than in children."

The following report of the case of a young soldier in which the temperature reached 109.2° F. (42.9° C.), with recovery, may therefore be of some interest.

CASE REPORT

A signalman aged 19 was admitted to a military hospital on Dec. 11, 1947, complaining of pains and stiffness affecting the wrists, knees, and ankles. He had had quinsy in childhood, hernia at 13, and appendicitis with peritonitis in July, 1947. There was no history of scarlet fever, rheumatic fever, or growing pains.

He had been quite well until the evening of Dec. 9, when he suddenly felt tired, shivery, and generally "out of sorts," and complained of sore throat and pains in both shoulders and upper arms. Next day these symptoms were still present, with frontal headache and dizziness on moving about. On Dec. 11 he started to get pains and stiffness in the knees, ankles, wrists, and elbows. He noticed that his left knee was swollen. He vomited twice that day. On admission to hospital he felt weak and ill, his throat was still sore, and the joint pains were still severe. He had also constant dull pain in the precordial area. His appetite, normally good, had been poor since the onset of symptoms and he had become constipated. There was no cough or sputum; nor were there any urinary symptoms.

On examination he was flushed and ill, the tongue was moist and coated, and the throat slightly injected. The mucosae were normal. No rash, no palpable nodes, and no cyanosis or clubbing were present. The temperature was 100° F. (37.8° C.), pulse 94, and respirations 20. The heart was not clinically enlarged. The heart sounds were normal at all areas; there were no murmurs. The blood pressure was 130/75.

Respiratory system: no dullness; sounds vesicular all areas; no adventitious sounds. The abdomen was lax, with some tenderness in the left upper quadrant. The liver, spleen, and kidneys were not palpable. The central nervous system showed no disease. There was pain on passive movement of wrists, elbows, knees, and ankles, with redness and swelling of the left knee. The urine showed no abnormality. On *x*-ray examination the heart and lungs appeared normal. White blood cells numbered 7,300 (N. 77%, L. 18%, M. 3%, E. 1%, B. 1%). Acute rheumatism was diagnosed and salicylate therapy started.

Progress.—The joint symptoms responded to salicylates, and after the first few days in hospital the patient was free of joint pains and stiffness. The pyrexia, however, gradually increased. On Dec. 17 a pericardial friction rub was audible over the greater part of the cardiac area. The temperature was 102° F. (38.9° C.). On Dec. 19 the area of cardiac dullness had increased and the rub had disappeared. *X*-ray examination confirmed gross cardiac enlargement with pericardial effusion. By Dec. 20 the pyrexia had become remittent in type, reaching 104–105° F. (40–40.6° C.) each evening. White blood cells numbered 21,000 (N. 89%, L. 9%, M. 2%).

On Dec. 23 blood culture was sterile. Agglutination tests for the enteric group of organisms and *Brucella abortus* and *Brucella melitensis* were negative. Pericardial puncture yielded 20 ml. of evenly blood-stained serous fluid. Films showed lymphocytes and polymorphs in equal numbers, and no organisms. Culture was sterile.

Despite negative findings it was deemed advisable to start penicillin therapy—50,000 units three-hourly. There was no response to chemotherapy. The temperature continued to swing, reaching 106.4° F. (41.3° C.) on Dec. 25 and 109.2° F. on Dec. 26. Immediate cold sponging and the application of ice-bags lowered the temperature to 105° C. (40.6° F.) within fifteen minutes.

On Jan. 2, 1948, the patient was unable to take fluids and became very dehydrated. Chlorides disappeared from the urine.

X-ray examination showed gross pericardial effusion hiding the lung as far up as the second rib anteriorly, with opacity of the lung above, due to collapse. He was given intravenous saline and by Jan. 5 the dehydration had improved and he was again taking fluids orally. Further needling of the pericardium yielded similar blood-stained fluid containing a moderate number of white blood cells, mainly lymphocytes. Both these specimens gave no growth on culture for acid-fast bacilli. From this date the temperature gradually fell from 103–105° F. (39.4–40.6° C.) to normal.

On Jan. 15 *x*-ray examination showed some diminution of the heart shadow and there was a definite improvement in the general condition. Blood examination showed: red cells, 2,560,000; Hb, 8 g. %; M.C.H., 31 $\gamma\gamma$; white cells, 5,900 (N. 51%, L. 42%, M. 7%).

Convalescence continued satisfactory over the next four months, apart from a marked degree of anaemia which responded slowly to iron therapy. On May 10 the patient was transferred to a hospital near his home. His general condition was excellent and he had put on a considerable amount of weight. Clinically the heart was not enlarged, the heart sounds were normal, and no murmurs were audible. A radiograph showed the heart shadow to be within normal limits. The B.S.R. was 28 mm./hr. Blood examination showed: red cells, 4,300,000; Hb, 10.7 g. %; M.C.H., 22 $\gamma\gamma$; white cells, 9,400 (N. 62%, L. 31%, M. 5%, E. 2%).

I am indebted to Lieutenant-Colonel E. H. P. Lassen, R.A.M.C., for permission to publish this case, and to Major T. B. S. Dick, late R.A.M.C., for assistance and advice.

DOUGLASS W. TAYLOR, M.B., Ch.B.,
Captain, R.A.M.C.

Self-castration

The following case seems to be rare enough to justify publication.

CASE REPORT

A man aged 34 was brought to the casualty department by ambulance on July 10, 1947, at 8.50 p.m. He stated that he had removed both his testicles with a razor two hours previously: he was an epileptic, and had been told that castration would effect a cure. He appeared to be healthy and robust, and in complete possession of his senses. He had a severe lacerated wound of the scrotum, which was not bleeding very severely. He was not at all shocked, and was very garrulous. He seemed quite well satisfied with his action, which he had been contemplating for some time. This was evidenced by such statements as, "Well, I have done it now, doctor."

On examination the scrotum had a large lacerated wound on the anterior wall, which had been literally ripped open. Both compartments of the scrotum were filled with blood clot, making it difficult to assess the amount of trauma to the cord and soft tissues. He had his testicles in a small cloth bag, which he stated was his "money bag," and this was rolled up in the front of his vest. He produced these with an air of great satisfaction. The calmness with which his actions were performed was very remarkable.

In order to gain sanction for the necessary operation the patient was solemnly asked if he would sign the following statement: "I ..... state that I cut my testicles out to-night with a razor blade, and I consent to an operation." This was done before operation to provide legal cover in the even of any subsequent action after the patient had realized his deformity.

At operation the lacerated ends and the bleeding-points of the spermatic cord were secured and ligated and the scrotum was closed with a small drainage-tube. He was treated with penicillin and made a good recovery from the effects of the operation. The wound healed within two weeks.

In view of the comment excited by the case, and as he was obviously an undesirable patient to keep in the general ward of a hospital—he made no secret of his act, and was indeed rather proud of himself—he was transferred to the county mental home next day. He was subsequently shown at a clinical meeting, when his attitude had not changed. Up to the time when last seen (July, 1948) he had had two fits, but was under suitable mental treatment.

R. D. N. BISSET, F.R.C.S., D.A.

According to the *Manchester Guardian* a report presented to the Leeds Executive Council showed that during the first nine months of the National Health Service in Leeds the general medical services cost £372,094, prescriptions £224,097, general dental services £280,751, ophthalmic services £173,397, and administration £15,670. The total expenditure of more than one million pounds was equal to £2 a head of the population. The 484,000 people on doctors' lists shared more than two million prescriptions, obtained 35,500 pairs of glasses, had 75,000 sight tests, and paid 48,663 visits to the dentists.

Reviews

EAR, NOSE, AND THROAT

Diseases of the Ear, Nose, and Throat. By D. G. Carruthers, M.B., Ch.M., F.R.A.C.S. Second edition. (Pp. 344; 140 illustrations. 25s.) Bristol: John Wright and Sons. 1948.

L'Exploration Clinique en Oto-Rhino-Laryngologie. By Georges Portmann. (Pp. 934; 541 illustrations. 2,500 francs.) Paris: Masson et Cie. 1948.

Mr. D. G. Carruthers's small book, hailing from Sydney, is written for students who want to learn the elements of the subject. No controversial theories are discussed, nor are major operations described: the subject matter is simple and practical. The first chapter describes the examination of the nose, throat, and ear, with helpful illustrations, and gives several "tips" for the comfort of the patient and the success of the observer. The coloured plate depicting various appearances of the tympanic membrane is good, though one of them might with advantage have shown a marginal perforation. Hearing tests are briefly dismissed; after advocating the spoken word as the most practical test and mentioning gramophone audiometry, it seems a pity the author added the forced whisper and the watch test. The explanation and illustration of the labyrinth tests are good.

There follow sections devoted to the diseases of the individual parts of the upper respiratory tract, beginning with the throat. The operations for removal of tonsils and adenoids are fully described and illustrated. In the discussion on retropharyngeal abscess and its treatment mention of such a rare complication as erosion of the internal carotid seems out of place. Again, in describing syphilis of the pharynx the author states, "A primary lesion takes the form of a shallow and slightly indurated ulcer." In this country a primary syphilitic lesion of the pharynx is extremely rare and does not take the form of an ulcer. Exception may also be taken to lack of emphasis that tuberculous ulceration of the pharynx is only seen as a complication of advanced phthisis.

The section on the nose and sinusitis wisely recommends a conservative line in treatment, that every effort should be directed to restoring the nasal lining to normal. For chronic sinusitis standard operations are advocated, but an external fronto-ethmoidal operation surely may be classed as a major procedure. In several instances antibiotic chemotherapy is advised, but is given second place to surgery. Again, it is unfortunate the author states that a common cause of headache of nasal origin is reflex irritation from sharp septal spurs and ridges, a view long abandoned in this country.

The next part deals with the ear, and is perhaps the best in the book. The pages on meatitis are excellent; obviously the author has had very wide experience of every variety. His advice on chemotherapy in acute otitis media is exactly what is needed by the student. In the description of acute mastoiditis the indications for operation are good, but should include deafness and facial paralysis. Lastly comes the section on the larynx. Acute and chronic laryngitis are described, but one complication of the former—ulceration and perichondritis—is surely too rare for inclusion. The discussion on paralysis of the cords is the weakest part of the work. There is no description of the muscles that move the cords, and one sentence must leave the student in doubt whether only the left recurrent nerve passes round the aorta. Further, a page of pictures of the larynx to show the various positions of the cords in different kinds of paralysis is upside down. There follows a good description of the operation of tracheotomy. Other chapters discuss foreign bodies in the air and food passages, diseases of the oesophagus (with good *x*-ray pictures), internal-ear deafness, and the use of hearing-aids.

In *L'Exploration Clinique en Oto-Rhino-Laryngologie* Docteur Georges Portmann asserts that the clinical approach to the patient is vital, and unless the doctor has this clinical knowledge all his scientific learning is useless. He emphasizes throughout the importance of symptoms and signs, and this monumental work fully justifies his claim to carry out his task; the student who had never seen a patient could, if he read and followed the instructions exactly, examine the ear, nose, and throat adequately. The method of taking the history is fully explained. Normal appearances and methods of examination are clearly described, and in some cases every step is illustrated not only by diagrams but with excellent photographs; as an example, the passage of the Eustachian catheter is given eight pictures.

There are six sections: ear; nose; mouth and pharynx; larynx, trachea, and bronchi; oesophagus; laboratory examinations.

The description of the examination of the ear is detailed, profusely illustrated, and includes the anatomy and physiology. To explain the internal ear there are several reproductions of microscopical sections. Functional examination of hearing is fully discussed, and the analysis of the reactions of the labyrinth occupies many pages, every stage being shown in photographs. Radiography of the mastoid is demonstrated in various positions. The same meticulous care and detail is devoted to the examination of the nose and naso-pharynx. The author uses a special naso-pharyngoscope and a sinuso-pharyngoscope with which the cavity of the antrum can be studied.

The section on the mouth and pharynx includes a description of sialography and explains how radiographs of the pharynx and the teeth should be taken. Chapters on the larynx, trachea, and bronchi open with a detailed account of the anatomy (as in all other sections), after which the voice and the use of the stroboscope are considered. There follow a great number of illustrations of various methods of direct examination, including the suspension laryngoscopy of Killian, which is now rarely used in this country. The gastroscope also has a place in this part of the book.

The work ends with a full description of laboratory methods, which is not considered necessary in English books on the specialty. The compilation of this tome, the work of one man, must be regarded as a fine achievement.

W. M. MOLLISON.

PSYCHOBIOLOGY

Psychobiology and Psychiatry. By Wendell Muncie, M.D. Second edition. (Pp. 620; 70 illustrations. £2 5s.) London: Henry Kimpton. 1948.

Psychobiology is a school of psychiatry initiated by Dr. Adolf Meyer. Under Meyer's leadership the Henry Phipps Clinic at the Johns Hopkins Hospital became a teaching centre of international repute. Many teachers in key positions in this country studied there under Meyer, whose doctrines have therefore exercised an important influence on British psychiatry.

Psychobiology has three significant aspects: a philosophy, a mode of approach to the patient, and a framework for clinical description. From the philosophical point of view it is monistic, demanding that the individual should be treated as a unity and not in the separate categories of body and mind; and it maintains that the laws of behaviour are distinct from, and of a higher order than, those of physical medicine, as the laws of chemistry are not directly to be derived from the concepts of physics but have a validity of their own. The psychobiological approach to the individual patient is mainly directed to an effort to understand his behaviour as the resultant of past experiences and present circumstances. Mental disorders are conceived as reactions; the approach is biographical, the concepts employed are dynamic. Allowance is made for organic and constitutional factors; but every attempt is made to account for as large a part as possible of the total picture in terms of what is individually rather than generally significant. So it is that such concepts as that of the "endogenous" psychoses come to have little meaning, and even the specific features of organic states tend to become submerged under the emphasis given to the total reaction of the individual.

Standing midway between the classical psychiatry which stems from Kraepelin and the pan-psychic theories developed by the psycho-analysts, psychobiology has been assailed from both sides. From the point of view of the former, its principal weakness is that it leaves little room for the specific

states derived from organic process and hereditary predisposition. The strength it gains in therapy is lost in the fields of diagnosis and prognosis. As the individual patient always remains an individual, features shown in common by groups of patients receive scant attention. It has accordingly proved remarkably sterile in stimulating research, and in this respect cannot be compared with either neo-Kraepelinian psychiatry or psycho-analysis. From the psycho-analytic side it is criticized for the insufficient emphasis it places on the unconscious and for its neglect of free association as a technique of investigation and treatment. In the United States its position has become weaker, and it seems that it will disappear under the rising tide of adherence to the Freudian school. Nevertheless, it has important advantages over both the opposed trends. It has corrected the too static concepts of the older psychiatry, and has especially fructified the study of the neuroses. In this field some of its concepts are indispensable, and it is probably the best available discipline for the student of psychotherapy. Compared with psycho-analysis, it has the great advantages of retaining the medical viewpoint and of being balanced, scientific, and undogmatic. Every student of psychiatry, no matter to what school he is drawn, should read Dr. Muncie's exposition.

ELIOT SLATER.

FEMALE SEX HORMONES

Die weiblichen Sexualhormone in der Pharmakotherapie. By O. Mühlbock, H. Knaus, and E. Tscherne. (Pp. 300; illustrated. 24.80 Swiss francs.) Bern: Medizinischer Verlag Hans Huber.

This book on therapy by female sex hormones is one of a series intended to discuss the treatment of individual diseases and the uses of various therapeutic substances. It opens with a section on the biochemistry, physiology, and pharmacology of oestrogens and progesterone. The chemical structure, preparation, site of formation, and metabolism of the steroids are dealt with in turn, and methods of chemical and biological assay are mentioned. A brief description is then given of the action of the hormones on the reproductive tract and other organs in the body. This general introduction adequately fulfils the authors' intention of providing a summary of reasonably accepted knowledge for practising doctors.

The second part of the work is concerned with the use of female sex hormones in clinical practice. It is illustrated by clear diagrams and describes the hormonal treatment of menstrual abnormalities, pregnancy, and sterility. The methods proposed do not conflict with current practice in this country. The final section treats of the use of oestrogens in endocrine disorders, in circulatory disturbances, and in dermatology, urology, psychiatry, and other branches of medicine. Much of this matter consists of summaries of uncontrolled observations reported by clinicians who on purely empirical grounds have found oestrogens beneficial. This section may provide ideas for treating refractory cases, but it is not based upon sufficient scientific knowledge. It is remarkable that the strikingly successful use of oestrogen in the palliative treatment of cancer of the prostate is not mentioned at all.

P. L. KROHN.

The third edition of *Handbook of Orthopaedic Surgery*, by A. R. Shands and R. B. Raney (pp. 574; 159 illustrations; $6.00 or £1 12s. 6d. St. Louis: The C. V. Mosby Company; London: Henry Kimpton), has apparently been found of great value as an adjunct to undergraduate orthopaedic study in the United States, where many of the leading medical schools dispose of the subject in twenty-four lectures of an hour's duration. Accordingly, this work is divided into twenty-four chapters, which provide a sound and comprehensive outline of orthopaedics. The book is excellently produced and beautifully illustrated, with the exception of the radiographs, which are generally not reproduced photographically but represented by artists' drawings. Although this has been done to eliminate unnecessary detail it introduces a confusing element of unreality. The work is naturally deficient on those aspects of orthopaedics which in any case cannot be learnt from books—namely, after-treatment and splintage. One of the best features is a really excellent bibliography, providing a valuable "source book" of orthopaedics, a feature which will appeal greatly to the postgraduate student.

BOOKS RECEIVED

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 9 1949

THE ANNUAL MEETING

Last year the Annual Meeting was held at a time when the medical profession was full of anxiety about the introduction of the National Health Service. It was fitting, therefore, that the B.M.A. then met in an ancient university town, where it could be reminded that the advancement of learning was something but little affected by the shifting political scene. In spite of difficulties those responsible for arranging the Cambridge meeting set a very high standard for those who were to succeed them as hosts year by year. The Harrogate Division, under the new President of the B.M.A., Dr. C. W. Curtis Bain, rose to the occasion with conspicuous success, and the meeting last week had much of the flavour and atmosphere of annual meetings held before the war. Harrogate turned out to be an ideal place for a conference of this kind. Not only was the setting full of charm and good weather, but the buildings in which business was conducted and the visitors were lodged were so conveniently grouped in the centre of the town that it was easy to pass from one to another without fatigue and on foot. The fact that the meeting ran so smoothly is indeed a tribute to the remarkably efficient organization behind it. Dr. and Mrs. Bain were the most delightful and unassuming of hosts. Upon the honorary local general secretary falls much of the burden of organization, and in Dr. D. D. Payne, Medical Officer of Health for Harrogate, the Division had found the right man for the job. He was ably helped by Dr. T. A. Best, Mr. T. V. Pearce, Dr. T. G. Reah, and Dr. L. J. Prosser in providing for the comfort and entertainment of the guests not only from this country but also from overseas. The civic authorities under the Mayor, Councillor Mrs. M. Fisher, J.P., worked obviously in the closest co-operation with the local medical profession to make the week in Harrogate memorable and enjoyable.

If Harrogate was a social success, it was no less a success intellectually. One of the principal reasons for holding the meeting is to provide through the scientific sections an opportunity for the visitors to hear from authorities what they know and think about current medical progress. For the first time four days instead of three were given to the scientific sections, an innovation introduced by the honorary local science secretary, Dr. J. V. Wilson, to whom the B.M.A. is much indebted for the first-class and varied intellectual fare last week. The Sections were very well attended, and in most of them there was time and scope for discussion.

Before the main body of visitors arrived the Annual Representative Meeting, at which there was a record attendance, had spent three and a half days in debate on the various matters now preoccupying the mind of the profession generally. In fact the agenda was so heavy that, in spite of the efficient conduct of the business by Dr. E. A. Gregg, the Chairman, there was not enough time left on the last morning to deal adequately with many important committee reports. Two subjects stood out in the meeting, on one of which there was complete agreement and on the other of which there was disagreement. On arbitration the Representative Body enthusiastically followed the lead given to it by Dr. H. Guy Dain, and comment on this appears in another leading article. On the organization of the B.M.A. the R.B. once more found itself with a divided mind; the proposals before it were the result of the most thorough examination by the Organization Committee and the Council. The debate on this, which was fully reported in last week's *Supplement*, at least shows that representatives take a lively interest in the question how the B.M.A. should adapt its structure to changing conditions. Apart from the question of how, for example, members should be elected, the desire seems to be for a larger representation on the Council of the B.M.A. This is understandable and supported by argument. It may nevertheless be asked whether an increase of size makes for an increase of efficiency. The whole question of organization has once more been referred back, and it is probable that a special representative meeting will have to be called to look into this highly important problem. The meeting, preoccupied as it was with the present and the future, did not forget the past, and earnestly considered how best it might commemorate those medical men and women who lost their lives in the war. It decided finally to adopt the Council's suggestion that there should be a visible and permanent memorial in the shape of a fountain in the courtyard of B.M.A. House, Tavistock Square.

No meeting of professional men is complete without the ceremonial and ritual which give it cohesion, strength, and dignity. In spite of the heat of the day a large procession wended its way to the church on Tuesday, where it had the privilege of hearing a sermon by the Archbishop of York. The Adjourned Annual General meeting was once more, and this time with greater significance, made colourful by the introduction one by one

of delegates from overseas. On this occasion the Gold Medal of the Association awarded to the late Dr. John W. Bone, who for many years held office, including that of Treasurer, in the B.M.A., was presented to his son, Mr. Alan W. Bone. The popular lecture at the conclusion of the meeting was attended by a full gathering of the people of Harrogate to hear Dr. Charles Hill's well-known voice on the subject of "Health and Happiness."

At each annual meeting the Association, in electing its President for the coming year, also chooses the man as President-Elect who is to be the next to preside over the B.M.A., the choice this year being Professor T. P. McMurray, the well-known orthopaedic surgeon in Liverpool. If Liverpool succeeds in emulating the example set by Harrogate then we may be sure that the large numbers who attended this year's meeting will be present next year in a county whose rivalry with Yorkshire has been told so often in the history books.

ARBITRATION

During the second reading debate on the National Health Service Bill in May, 1946, Mr. Greenwood, replying for the Government, pointed out that the Minister was given power to prescribe by regulations the conditions of service and remuneration of those employed in the National Health Service. He went on to say that Mr. Bevan's intention was to use "the familiar machinery of discussion and negotiation with employees" before prescribing terms of service or rates of remuneration. Where suitable machinery existed it would be used with such adaptations as might be necessary. "What my right hon. friend [Mr. Aneurin Bevan] has in mind where there is no machinery is to set up some machinery of the Whitley Council type, behind which there may be provision for agreed reference to arbitration." In view of what has happened since, we should draw attention to the words "may" and "agreed." In May, 1948, the Minister agreed that after the inception of the Service it would be open to the profession to raise through Whitley machinery the question of betterment. It was because of this that the chairman of Council, Dr. H. Guy Dain, was able to persuade the medical profession to enter the National Health Service. A document setting forth the Government's proposals for Whitley machinery was sent to the B.M.A. in October, 1947.[1] In this the following statements appeared: "It will suffice here to say that, while the Government hopes that the normal working of Whitleyism will minimize the necessity for arbitration, it is anxious to accord the fullest rights to arbitration subject to the preservation of the Government's prerogatives. *A code of conduct is unlikely to be arbitrable, but a simple proposal for a change in wage or salary rates almost certainly is.*" (Our italics.) But when representatives of the General Medical Services Committee went to the Ministry of Health in April of this year and asked whether the question of remuneration for general practitioners could be raised through Whitley machinery and, in the event of disagreement, if recourse could be had to arbitration, it received this reply: "It must not be assumed without further discussion that participation in the Whitley machinery necessarily involves, in the event of disagreement, the right to resort compulsorily to arbitration on all subjects."[2]

The Minister is under a moral obligation to provide machinery for arbitration in the event of disagreement on the remuneration of those medical men and women working in the National Health Service. What betterment factor should be applied to the remuneration of general practitioners and consultants and specialists so as to carry out the recommendations of the Spens Reports is now being discussed. In the event of disagreement it is imperative that the right to arbitration should be granted and Ministerial promises thus be met. As Sir Lionel Whitby pointed out in a recent letter to *The Times*,[3] under Clause 12 of the Amending Bill, the Minister of Labour has the power to refer disputes to arbitration and is unlikely to do this if the Minister of Health does not want it to be done. Sir Lionel asks why the Government have gone back on their pledge and are proposing to treat professional workers less fairly than the rest. He points out that the implications of the Government's attitude are far reaching, as more and more professional workers are becoming employed by the State indirectly or directly. This is not a question affecting only medical men and women, and it is because of these wider implications that the medical profession must press for a satisfactory settlement of a matter which weekly becomes more confused by this or that interpretation of this or that mechanism. As the Secretary of the Association pointed out at Harrogate, the profession had been promised that the voluntary arrangements under the Whitley machinery should be buttressed by an arbitration system. A constitutional issue was raised by the fact that remuneration would in due course be the subject of regulations. Now that so much of industry is nationalized and the medical profession also, the Government has lost its function as a balancing mechanism between two sides in a dispute, as it now becomes a party in disputes in nationalized industries and professions. If this country is to preserve its reputation for justice and fair play it is essential that in disagreements between the Government as employer and, for example, the medical profession as employee there should be as a matter of principle a method of referring such disputes

to arbitration in a way that will allow the medical profession to do its work free from a feeling of grievance. Arbitration has already been the subject of two recent articles in this *Journal*,[4 5] and we make no apology for returning to this theme once more.

The Joint Committee representing consultants and specialists decided on Tuesday afternoon to advise consultants and specialists not to sign permanent contracts. In a letter sent to the Secretary of the Ministry of Health (and published in the *Supplement*) Sir Lionel Whitby, as chairman of the Joint Committee, asks that there should be established for consultants and specialists a permanent negotiating machinery, and that disputes (including those on remuneration) should be referable to arbitration, both parties to be bound by the decision of the arbitrator. As Dr. Dain said at Harrogate: "We must have the right to go to arbitration even though it is the Government which is the employer. It is essential to us if we are to continue in the Service that freedom to go to arbitration should never be in question."

PAST AND PRESENT

Dr. H. Guy Dain this year did not seek re-election as chairman of Council, and thus brings to an end a memorable period of office. Dr. Dain was elected chairman in 1943 and during the past six years has been in the forefront of the controversy that has raged over the National Health Service. At no time in the history of the B.M.A. has a chairman of Council had to bear such a heavy load of responsibility. At no time have the decisions and actions of the chairman been of such consequence to the medical profession. Amid conflicting counsels and changes of mood in the profession Dr. Dain has with courage and tenacity kept clearly in front of him —and in front of the doctors of this country—the principal policies of the British Medical Association. With this he has combined a remarkable grasp of detail and a capacity to expound before medical meetings both the particular and the general in forthright and orderly English. This he has done with an energy and endurance that might be expected of a man one or two decades younger than himself. It is indeed difficult to recall that he was in 1917 a member of the Insurance Acts Committee, of which he became chairman; his services for the medical profession under the N.H.I. Acts were recognized in 1936 when he received the Gold Medal of the B.M.A. It is good to know that he has agreed to continue taking an active part in Association affairs by serving on its Council and on many committees.

It can be no easy task to follow Dr. Dain, but, like him, the new chairman of Council, Dr. E. A. Gregg, has been chairman of the Insurance Acts Committee and of the Representative Body. He therefore brings to his new and distinguished office a long and well-tried experience in medical politics and a capacity, too, to give unstintingly of his time and energy to the affairs of the Association. There are in the coming year also changes in the membership of the Council, and fourteen doctors will for the first time take part in its deliberations. There is provision in the Association's constitution for the past President to be a member of Council, and in this capacity the Association will continue during the next year to have the advantage of Sir Lionel Whitby's interest in and grasp of the business of a body which can through its membership speak for the profession as a whole.

WILLIAM OSLER

We celebrate this week the centenary of the birth of a great physician—"a physician of two continents"—for William Osler's name is honoured as much in Canada and the United States of America as in Great Britain. In paying tribute to Osler's memory we have been helped by six men who knew him well and whose memories of their friend bring him vividly before the reader thirty years after his death.

Sir Charles Sherrington, who as Professor of Physiology at Oxford worked closely with the Regius Professor of Medicine, tells of Osler's influence there as a scholar, humanist, and physician. In modern times Oxford has received many professors from other universities, but there can have been no worthier adopted son or one who so speedily became imbued with its spirit and tradition. Professor Charles Singer speaks of Osler's love of old books and manuscripts: "He was a true book-lover, to whom the very sight and touch of an ancient document brought a deep and subtle pleasure." Professor Singer also discerned in him, despite his gaiety, a profound and essential melancholy, as of one who had passed through some unknown tragedy to a life of human service. This trait was accentuated in Osler's last years by the loss of his only son.

Osler's cousin, Dr. W. W. Francis, who worked under him at Johns Hopkins University and completed the *Bibliotheca Osleriana* in a spirit of scholarly devotion, contributes an interesting account of the Osler family rich in new biographical detail. Lord Horder, who attended Osler in his last illness, emphasizes his encouragement of, and interest in, a younger colleague. Professor K. J. Franklin pays tribute to Lady Osler. As he says, "It is impossible to overrate what she did to stimulate 'the great physician,' to help him to make right decisions, to provide him with necessary recreation at home, to entertain their numerous friends while leaving him free for his work, and in countless other ways to be his ideal partner for twenty-seven eventful years." Lady Osler was a great and good woman, and no tribute to her husband's memory would be complete without reference to the important part she fulfilled as wife and helpmate. Lastly, Sir Arthur MacNalty contributes a biographical study of Osler based on personal knowledge of the great physician during his years at Oxford.

The life of Osler falls into three distinct periods: the Canadian period, during which he did his scientific researches as zoologist, physiologist, and pathologist and taught the new learning in medicine at McGill University; the American period, in which at Philadelphia he enhanced his reputation as teacher and physician and afterwards as Professor of Medicine at Johns Hopkins University built up a famous medical school from the beginning; and the Oxford period, in which he not only served the Oxford Medical School but advanced British medicine and became one of its recognized leaders. Here too he found opportunity for gratifying his love of letters and for welding closer links between Britons and Americans, links which have been of paramount importance in two world wars. In the 1914–18 war Osler himself rendered conspicuous service as a consultant and adviser to the War Office.

Osler was an outstanding figure in medicine in his day and generation. He was the author of an original and widely read textbook of medicine, based on personal experience. He first described the blood platelets in the circulating blood; he made a number of observations on some rare diseases, two of which bear his name; he wrote monographs on medicine, lectures, and historical studies of men and books; and he was an able teacher and medical administrator. But these facts are insufficient to explain the great influence that he exercised on his contemporaries and on medical progress, or to render it apparent to a younger generation. The answer to this question will be found in the contributions from his friends and students assembled in this issue of the *Journal*. Throughout each and all of these tributes, like a golden thread in a variegated tapestry, runs, in addition to profound admiration for Osler's intellectual gifts, a reference to his humanity and the magnetic charm of his personality. Everybody who met Osler at once became his friend—high and low, rich and poor. The child, the student, the colleague, the old men at Ewelme, all realized that in Osler they had found a sympathetic confidant. This gift of approach to men and women was aided by his marvellous memory for faces. It was said of Osler that he never made an enemy. He never spoke unkindly of anyone, and, realizing the imperfections of mankind, sought out the best in everyone. Like St. Martin, one snowy night in Baltimore he gave his cloak to a beggar, who in return bequeathed to "my good friend William Osler" his liver, hobnailed by drink.

In some respects Osler was a saint of medicine, yet, as his practical jokes showed, a very human saint. He spent himself freely for others, for the honour and dignity of his profession, and for the common weal. He declared that happiness lies in absorption in some vocation that satisfies the soul; that we are here to add what we can to, not to get what we can from, life, and he lived up to that belief.

EARLY WEANING

Is breast-feeding on the decline? General impressions are that it is; on the other hand, history records that from the time that infant feeding became the subject of special study in this country there have always been many mothers unable or unwilling to suckle their babies. Fashion, fancy, poverty, ignorance, and social trends have all in their day had the blame attributed to them. So has the mother-in-law, despite the fact that breast-feeding has no more effective propagandist than the mother-in-law who has herself nourished all her family on the breast. The influence of these various factors changes with the times, and without more reliable evidence it would be unwise unreservedly to accept that the mothers of to-day are less inclined to breast-feed than those of previous generations. If there is reason to doubt an absolute decline in the incidence of breast-feeding there is more justification for believing that a tendency exists for breast-feeding to be terminated earlier than hitherto. Spence[1] drew attention to this before the last war, and evidence in support of his views was later put forward by Robinson[2] and Hughes.[3] In last week's *Journal* (p. 14) Dr. F. H. M. Dummer described a recent investigation in Hertfordshire. He found that only 13.2% of babies were still wholly breast-fed at the age of six months, and he pointed out that the "mode" in breast-feeding is set by the primiparae. Physical incapacity on the part of the mother or infant is a relatively rare cause of failure to continue breast-feeding. Failure is not infrequently ascribed to "physiological insufficiency." Dummer rightly criticizes the use of the term, for it includes many ill-defined causes concerning which little is known, no matter how suspect they may be.

In a Ministry of Health report[4] the opinion was expressed that a rigid feeding routine in institutions may have an adverse effect on breast-feeding. This view finds its extreme form in the self-regulating feeding programme recommended by Aldrich and Hewitt.[5] Obviously there is a need for compromise between a routine rigidly imposed and self-regulation freely allowed. Allowance must be made for the emotional disturbances which are experienced by the recently delivered mother and which tend to be aggravated when she returns home from hospital—a crucial time for the successful maintenance of breast-feeding. Midwives, health visitors, and doctors who are themselves mothers are the readiest to testify to this fact and to its particular importance in the case of a mother recently delivered of her firstborn. Naish,[6] a staunch advocate of breast-feeding, has warned against irrational insistence on complete breast-feeding when convincing contraindications are present. A persistently hungry baby and a continuously miserable mother are poor advertisement for breast-feeding.

It is probable that insufficient use is made of complementary feeds as a temporary measure to tide over the difficult lactational phases which may occur in the first and third months after delivery. For success in the use of complementary feeds the full co-operation and complete

confidence of the mother have to be won. Perhaps it is failure to secure this that contributes to the trend towards premature weaning, for some mothers not uncommonly discontinue breast-feeding without seeking professional advice of any kind. Antenatal care offers valuable opportunities for obtaining the mother's confidence, and preparation for breast-feeding along the lines advocated by Waller[7] has much to recommend it on both physical and psychological grounds. Intimate, unhurried, and understanding advice, whether given in the home, in the antenatal clinic, or in the lying-in ward, encourages the mother to continue to seek guidance about the feeding and care of her infant. It is important that she should not feel that the continuity of professional advice is broken, and, ideally, the mother should be present with her baby when responsibility for supervision of a "case" is being transferred by the midwife to a health visitor. Mothers are quick to sense discrepancies in the views held among those who advise them, and continuance of breast-feeding is unintentionally discouraged on occasions by the variety of advice proffered. Overlapping is not uncommon and should be avoided.

Breast-feeding is a subject calling for joint research. More opportunities are needed for the general practitioner and his medical and nursing colleagues in the maternity and child-welfare services to exchange clinical observations. Craig[8] considers that the answer to many of the problems of premature weaning are to be looked for in the home and the clinic and not in the hospital; and that the answers, when forthcoming, may well call for revision of instructions given to pupil midwives, student nurses, and medical students.

THE HADAMAR TRIAL

The Hadamar Institution, near Limburg, in Hesse-Nassau, was a mental hospital up to 1940. In January, 1941, it was given the further duty of putting to death German nationals alleged to be mentally ill and with undefined prospects of recovery. In the first seven and a half months there were 10,000 of these killings, at first by gassing and later by "medications and injections." It was a condition of the work that it should be performed in secrecy. In June, 1944, this practice was extended to non-German nationals, chiefly Poles and Russians, who allegedly suffered from advanced tuberculosis. The Hadamar trial was concerned with this second series of killings, totalling 476. It was conducted in Wiesbaden during October, 1945, by a military commission appointed by the commanding general of the United States Army, Western Military District of Germany. Its proceedings[1] provide a fantastic record of the change which can take place in the outlook and standards of a hospital once the motive for its existence has been lost.

The medical officer, Dr. Adolf Wahlmann, was not the administrative head of the institution. Neither did orders to kill have to be given, because "these people came with the aim of being killed." They came "after they had been examined by a specialist for lung tuberculosis," or, as Dr. Wahlmann later said, "I cannot know that. They might have been general practitioners." These people "came and were killed without my seeing them. . . . They came and walked in through the main gate. Then someone called up—I don't know to whom, but not to me." Dr. Wahlmann's job was "to hand out the medications. That was my task, and without medications death would not have set in." He did not know the average dose: that was "left to my chief nurses," and "the pharmacy was open to the two of them, so to speak." There were bottles containing morphine, scopolamine, chloral hydrate, and paraldehyde, and tablets of "veronal," sulphonal, and "trional." In the morning, on his desk, he received a slip of paper that the patients had died in the night, and he went down to the cellar to make an inspection which was "not thorough." He did not feel their pulses, or use a stethoscope: "I had to rely on the fact that my chief nurses had determined the death beforehand." He agreed that some of the dead "looked remarkably healthy." His motive in inspection was "to protect the personnel in case somebody accused them of cruelties or injuries." Also he signed the certificates, assuming "besides the tuberculosis, [death] from a weak heart or some other disease." Dr. Wahlmann had qualified in 1903, retired on pension from mental-hospital work in 1936 on account of heart disease, was recalled to service in 1941, and sent a year later to the Hadamar Institution. He was sentenced to hard labour for life.

Those sentenced to be hanged were Alfons Klein, the administrative head of the hospital and a member of the Nazi party, and Heinrich Ruoff and Karl Willig, the male nurses who gave the "medications and injections." There were also three further sentences of hard labour. There is little medical interest in the case of Klein: he seemed anxious in evidence to justify the administrative decision that these killings should take place. Ruoff, one of the male nurses, emphasized that, as well as injections, "we did quite a bit of work with tablets." Morphine and scopolamine were in short supply, and the men took the tablets "without any trouble." The women, who did not like tablets, were given injections. So were the children.

The killings of German nationals were not the subject of the trial, but were admitted in evidence as giving the background of the institution. They were in fact the reason that Poles and Russians—presumed to be from the German slave-labour force—were killed in this way and in this place. Two points of interest were the secrecy of the operation and the concentration of the killing in only four institutions, of which Hadamar was one. As to the first, Dr. Quanbusch, ex-chief prosecutor of Wiesbaden, testified that four or five years before the trial he reported to his superiors his suspicions that German insane persons were being put to death in asylums. He was visited by the Chief Prosecutor from Frankfurt and told that all prosecutors and court presidents had been invited to a conference in Berlin where, after viewing some pictures of insane persons, they were shown a photostat copy of an order from Hitler authorizing the killing of insane persons by physicians in the institutions under certain undefined conditions. This was classified as a "State Secret Affair," and it was no doubt this secrecy which led to the concentration of killings in particular institutions. The result was that what had been a hospital became a place of execution, acting not on its own medical judgment—apart from principle—but on decisions taken by others.

INSTITUTES OF MEDICAL STUDIES IN THE U.S.S.R.

BY

V. LEBEDEVA

Director of the Central Institute of Advanced Medical Studies of the U.S.S.R.

The provision of facilities enabling physicians to undertake advanced studies to improve their theoretical knowledge and practical qualifications is an important part of the public health system of the U.S.S.R. In the Soviet Union the advanced training institutes for physicians at the hospitals, polyclinics, maternity homes, maternity and child-welfare centres, and medical educational institutions are under the central authority of the State, which organizes and finances them.

The Soviet Government has issued a number of decrees on advanced medical studies. After every 3 to 5 years' work in the provinces every physician has the right to advanced training at State expense. During training he continues to draw his pay from his place of employment. The doctors attending the courses are provided with living quarters and all other conditions ensuring effective study.

Before the October revolution in 1917 Russia had only one institute for advanced medical studies. It was in St. Petersburg, and very few physicians could afford the cost of studying there. Only 9,906 physicians graduated from the institute in the 32 years of its existence (from 1885 to 1917), but in 25 years of Soviet power over 37,000 physicians graduated from it—that is, 1,500 a year, or five times as many as before the revolution.

The Soviet Government opened ten similar institutes in Moscow, Kazan, Kiev, Kharkov, Odessa, Minsk, Novosibirsk, Tashkent, Tbilisi, and Baku. The largest is the Central Institute, in Moscow, founded in 1930. Over 52,000 physicians have graduated from it in the 18 years of its existence—an average of 3,000 a year.

There are two systems of raising the qualifications of physicians: (1) Specialization—that is, learning a new medical specialty; and (2) advanced training, when the specialist gains further knowledge of an already acquired specialty. The course for advanced training used to be of 2 to 3 months' duration, but now it has been prolonged to 4–6 months and in some cases to 12 months.

This course covers the main branches of medicine—such as therapy, surgery, paediatrics—and also special subjects such as endocrinology, helminthology, laboratory testing, diet, remedial physical culture, and so on.

Physicians can improve their qualifications in various branches of medical science, including patho-physiology, pathological anatomy, and other theoretical disciplines.

The Central Institute

The Central Institute of Advanced Medical Studies has 49 chairs distributed among the three faculties of surgery, therapy, and sanitary hygiene. The teaching staff includes seven members of the Academy of Medical Sciences, six corresponding members, 43 doctors of medicine, and 111 masters of science (medicine).

The major clinics of the Central Institute are in the Botkin Hospital, the largest in Moscow. The chairs of theoretical subjects and of hygiene, such as epidemiology, microbiology, communal hygiene, food, and industrial hygiene, are part of the Institute's organization. The chair of public health is of special importance. The task of this department is to train skilled administrators and organizers of the public health service. The training course is 12 months.

The Institute maintains contact with its graduates through the consultation bureau, which advises them on various theoretical and practical subjects. Hundreds of physicians in the provinces are engaged in scientific work under the guidance of the Institute. In the second half of 1948 alone twenty physicians defended their theses on material received from the Institute.

The serial publications, *A Practical Physician's Library*, issued by the Institute and consisting of a number of monographs on problems of theory and practice, serve as an important means of contact between the physicians and the Institute. The Institute has its publishing house, which issued 40 books in about 500,000 copies in the last two years. It also has a library with 70,000 volumes.

The Central Institute sends its teachers out to various places. Some teams have already visited the Lithuanian, Latvian, Esthonian, Byelorussian, Central Asian, and Transcaucasian Republics.

One of the most important tasks of the Institute is training postgraduate students and housemen in all the medical branches represented at the Institute. This course of training is three years.

The five-year plan of the Ministry of Health envisages advanced training and specialization for most physicians. The major part of the plan will be carried out by the Central Institute of Advanced Medical Studies in Moscow.

LEBANON HOSPITAL FOR MENTAL DISEASES

The 50th annual meeting of the Lebanon Hospital for Mental Diseases was held in London on June 15, with Mr. H. Lyn Harris, chairman of the general committtee, presiding. The history of the hospital and its background was sketched by Mr. Albert Hourani, who gave a vivid picture of the primitive Lebanon of fifty years ago as compared with the modern republic. The hospital itself had shared in these changes. From being a place for the segregation of the mentally afflicted, and then a place for their treatment and relief, it had become a centre of demonstration, experiment, and training for work in mental diseases in the Middle East.

Dr. J. Tylor Fox, on behalf of the medical director, Dr. R. B. Robertson, presented the medical report. There were 454 patients admitted during 1948 and 375 discharged, both figures showing an increase of some 120 on the previous year; 320 patients were now in residence. Electric convulsion therapy was used during the year in 171 cases, chiefly of schizophrenia and affective psychoses, with recovery in 70, relief in 41, and temporary relief in 28. Prefrontal leucotomy had been undertaken by Dr. Jidijan, of the American University at Beirut, on two patients. This was believed to be the first time the operation had been performed in the Middle East. One interesting and important departure was the setting up of an out-patient neuropsychiatric clinic at Beirut. Dr. Tylor Fox said that the turnover of the hospital for its size was larger than that of any mental hospital in England. In physical treatment and in occupational therapy it was a pioneer in its part of the world. Four-year medical students from the American University went there for training in psychiatry. Even such a modern feature as the hospital club for staff and patients had been instituted. Short addresses were given by other sympathizers with the work, including the minister of the Swiss Church in London.

ROYAL SOCIETY OF MEDICINE

NEW HONORARY FELLOWS

Sir Henry Dale, O.M., who was re-elected for a second year as President of the Royal Society of Medicine at the annual meeting of the Society on July 5, presented on the same occasion diplomas to five newly elected honorary Fellows.

In making the presentation to Sir Ernest Rock Carling he referred to his innumerable activities, especially on the Radium Commission and the King Edward's Hospital Fund, and described him as a distinguished surgeon, a great servant of the community, and a valued counsellor in the Society. Dr. Brock Chisholm he greeted as a Canadian and as one who by virtue of high international office was charged with great responsibility for the co-ordination of medical activities over a large part of the world. He was most fittingly the first Director-General of the World Health Organization. The next

diploma was presented to a recent president of the Society, Sir Gordon Gordon-Taylor. Sir Henry Dale referred to Sir Gordon's distinguished record in the war, when he was "arrayed as it seemed with such natural fitness in the uniform of a rear-admiral." His eminence in surgery and his gift for imparting knowledge were recognized all over the world, as witnessed by the fact that Melbourne, Toronto, and Athens had honoured him with degrees. His readiness to serve the Society was a great support to its present president. The fourth diploma was presented, *in absentia*, to Dr. Alan Gregg, head of the division of medicine of the Rockefeller Foundation, who had shown most sympathetic understanding of the needs and true spirit of research. "I find it impossible to suppose," said Sir Henry Dale, "that any internationally constituted organization within any future which we can discern will be able to devise quite such wise and independent distribution of support for medical research on so completely an international basis as that which the Rockefeller Foundation has achieved with such success." The last recipient was Professor René Leriche, of Paris, who was described as one of the most fertile and original workers in the field of surgery. The president had a special interest in welcoming Professor Leriche to honorary fellowship, because he was an exponent of surgery which had its roots in experimental physiology. He specially mentioned his work on the surgery of the sympathetic system. He already held the Lister Medal for surgical research.

After the presentations the ordinary business of the annual meeting proceeded. The report of Council showed that the Society had 9,389 members, a gain of 360 on the year, and that 1,393 members were resident abroad. A vote of thanks was accorded to the retiring honorary secretary, Mr. W. A. Pool, and the retiring vice-presidents (that is, presidents of sections) and other members of Council.

CONGENITAL PULMONARY STENOSIS

SURGICAL TREATMENT

The second Alexander Simpson-Smith Memorial Lecture under the auspices of the West London Hospital Medical School was given by Mr. R. C. Brock on June 15.

Mr. Brock opened by saying that the relief of certain forms of cyanotic congenital heart disease had aroused considerable interest during the past two or three years. The present seemed a suitable time to review the position and to assess the results of the Blalock-Taussig operation and its modifications. The problem of the "blue baby" had always been a tragic one, but it was only since operation became possible that the incidence and the full tragedy of the condition had been manifest. Many of these children had been hidden away, confined to their house or room for the greater part of their lives. There were children as old as 6 who had never been able to walk.

The mortality during the first few years of life was high, and only a few patients who reached the twenties were able to carry on any useful employment. At the congenital heart clinic at Guy's Hospital during 15 months 340 cases (185 male, 155 female) had been seen. One in two reached the age of 7, one in five the age of 14, and less than one in 10 the age of 21. During those 15 months 24 patients had died while awaiting admission to hospital.

Although the operation carried a considerable risk, the risk in most cases was far less than that of leaving the condition untreated. It was not enough for the surgeon to acquaint himself with the technical details of vascular anastomosis, nor was it a type of surgery for the lone operator. Team work was essential, and at Guy's 15 people were actively engaged in the management of these cases. As soon as it became possible to operate on cases of this kind, accuracy in diagnosis ceased to be an academic refinement. Clinical assessment was of first importance, aided by routine radiography.

Pre-operative Assessment

Blalock and Taussig had pointed out that the cyanosis and disability were due to the mixing of the venous and arterial blood in the heart and to inadequacy of the supply of blood to the lungs; the most important element in their contribution was the elucidation of the part played by this second factor. Th pulmonary blood flow must be assessed in each case. By radio graphy and radioscopy it was possible to exclude those case in which there was evidence of plentiful or excessive blood flo in the lung, as shown by the degree of vascularity. Mr. Broc here illustrated methods of cardiac catheterization and angio cardiography. By angiocardiograms it was easy to demonstrat right and left shunt, and by studying the anatomical arrange ment of the vessels the surgeon could form an idea whethe they were likely to be suitable for anastomosis.

Owing to the smallness of the vessels, operation before th age of 2 was not recommended by Blalock. The policy at Guy' had been not to operate much before the age of 5. Olde children on the waiting-list could not with safety be left to wai as long as the younger. Blalock also, if possible, avoide operation on patients over the age of 20, and with this th lecturer fully agreed. The oldest patient operated on success fully at Guy's was aged 29.

Mr. Brock went on to describe Potts's operation, which ther had been a tendency to adopt because it appeared to be quicke and easier than Blalock's operation. If it was possible t mobilize the subclavian artery to make an effective anastomosis it seemed to him unjustifiable to use the aorta. In the choic between the subclavian and the aorta he could not feel it righ to choose the aorta; if anything happened to that importan structure there were no means of retrieving the situation. Th special advantage of Potts's operation was in those cases i which the subclavian artery was very small or very short. H felt that the use of the carotid or innominate artery could no be justified.

Blalock recommended an antero-lateral intercostal approacl but the lecturer himself had given that up after trial, preferrin a postero-lateral approach. He had also, after 50 cases, aban doned the approach from the right side. By working from th left side a very thorough examination could be made. Ther was a marked tendency for bleeding to occur after operatior and he made it a rule to drain the chest in every case. Tha was an important point for those who were intending t embark upon these operations.

Mortality and Results

In his latest report on 610 cases Blalock gave an overal mortality of 17%. In the first 50 cases at Guy's seven patient had been lost, a mortality of 14%. The total number of case in which Blalock's or Potts's operation had been employed wa 86, with 13 deaths, a mortality of 15%. Among these 86 wer a large number of very poor risks. Blalock stated the result to be excellent in 75% of his cases. Among the first 50 case at Guy's, in addition to the seven deaths, there were three i which there was no improvement, but in 66% the result wa described as "almost perfect." He mentioned the case of lad who previously could not walk 10 yards, but after opera tion was able to ride a motor-cycle. A young woman who wa rescued from a condition of helplessness by operation was no married and pregnant and the pregnancy was being allowed t continue.

Mr. Brock finally discussed pulmonary valvular stenosis an its relief by valvulotomy, which he had performed with succes in five cases, and also infundibular stenosis and its relief b direct operation, which had been achieved with success i five cases. All these cardiac operations, he said, cause considerable anxiety and raised many difficult problems, bu he felt that it was only by dealing with these cases that th feasibility or otherwise of such operations could be judged Although most of the present work was directed to the relief o congenital abnormalities, the relief of acquired heart lesion was now feasible in some cases, and here the knowledg obtained by the surgeon in dealing with congenital lesions mus help.

Reference was made by Mr. Brock himself, by General Nei Cantlie, who took the chair, and by Dr. Geoffrey Konstam who proposed the vote of thanks to the lecturer, to the promis ing young surgeon, Alexander Simpson-Smith, in whose memor the lecture was founded. Simpson-Smith was taken prisone at Tobruk. He made a gallant attempt to escape to the Britis lines, and his body was subsequently found.

Nova et Vetera

ST. THOMAS'S PARISH VESTRY RECORDS AND A BODY-SNATCHING INCIDENT

There is now available for those who wish to study them in the library at County Hall, London, a collection of books and documents of the vestry of St. Thomas's Parish, Bermondsey, which the L.C.C. has recently acquired. St. Thomas's parish comprised St. Thomas's Hospital on its old site, Guy's Hospital, and a small area around: Horwood's map showing the parish boundaries in 1819 is reproduced in Parsons's *History of St. Thomas's Hospital*.[1] It ceased to be a separate civil parish in 1899.[2] It has been suggested that it was a separate parish even before the church was built, and was certainly one in 1378.[3] For ecclesiastical purposes it was merged by Order in Council in 1898 with St. Saviour's (now St. Saviour's with St. Peter's), the parish and hospital church being to-day the chapter-house of Southwark Cathedral.

The muniments acquired by the L.C.C. cover the period from the latter part of the seventeenth century to the early part of the nineteenth. As is to be expected, there are references in the records to St. Thomas's Hospital and to Guy's Hospital. In 1703 the vestry declined to appoint a committee to negotiate with the former the exchange of almshouses for other houses "untill the Gouvrnors of the said Hospital have given ye vestry Satisfaction in Relation to the Vaults under our Church."[4] Another time there was amicable discussion on whether the parish or the hospital should pay for the "surplices."[5] The underwardens' accounts for 1754 include an item: "ye Hospitals Beadles £5."[6] At a vestry held in the school-room on March 22, 1805, it was reported that "the Treasurers of St Thomas's and Guy's Hospitals were authoris'd by their Committees to advance the Parish the Sum of £150, towards defraying the Expence demanded, on the failure of raising seven Men for the Army of Defence." As that left a deficiency of £58, the meeting decided to raise a shilling in the pound rate.[7] In 1815 there was friction between the parish and the hospitals about whether certain persons connected with the hospitals should pay rates. The parish won a test case at the Quarter Sessions. The counsel representing the vestry thereupon "proposed to give up the Cases of Mary Boyce the Cook of Guy's Hospital, and of John Spooner the Porter, Cathne Wheeler the Cook, Jane Wright the Matron, and Jas Patterson the Porter of St Thomas's Hospital, the aggregate amount of whose Rates was inconsiderable," if certain other appeals were abandoned.[7]

Body-snatching

From the medical point of view, however, perhaps the most interesting item in the records is the transcription in the minute-book in 1795 of a report of a general meeting held at the Crown and Anchor Tavern to consider the "lately discovered Depredations in Lambeth Burial Ground." The account given at the meeting states:

". . . It appeared, that the robberies of the said Burial Grounds, were discovered by three men being disturbed as they were conveying from thence five human bodies in three sacks, in the night of the 18th of February last.

"That in consequence of such discovery, people of all descriptions, whose relations had been interred in that Ground, resorted thereto, and demanded to dig for them; which being refused they in great numbers forced their way in, and in spight of every effort the Parish Officers could use, began like mad people to tear up the ground; at the same time, charging the Officers and every one that offered them any opposition, with being privy to the robberies, and in general terms threatening them: thus circumstanced, the Parish Officers finding nothing but down-right force, (and that of more strength than the civil power) could prevent the populace, and fearing to bring on a riot (which in its effects might produce the most serious consequences) after having used every effort, short of force, were necessitated to give way, and let the people go on in their searches; by which a great number of empty coffins were discovered, the corpses having been stolen from them; great distress and agitation of mind was manifest in every one, and some, in a kind of phrensy, ran away with the coffins of their deceased relations; and the generality of the populace were so ripe for mischief, that they attacked a house with stones and brick-bats, upon the bare suspicion that the occupier had been concerned in, or privy to the robbery of the ground, and it was with difficulty they were prevented from demolishing it.

"To restore order, and discover the offenders if possible, a large reward was offered, and the committee aforesaid appointed; by whose enquiries, it was found that the Grave Digger, and three other persons were the robbers, and that the bodies had been conveyed away in a coach to different people for various purposes, as was made appear to them by informations upon oath; the material parts of one of which informations being now read, showed, that within the knowledge of the informant, eight surgeons of public repute, and a man who calls himself an Articulator (and by hand-bills openly avows the trade, exclusive of others of less note) are in the constant habit of buying stolen dead bodies, during the winter half year; in whose service the following fifteen persons are generally employed, namely, Samuel Arnot, alias Harding; John Gilmore, Thomas Gilmore, Thomas Pain, Peter McIntire, alias Mc Intosh, James Profit, Jeremiah Keese, Moris Hogarty, —— White, a man called Long John the Coachman, John Butler, John Howison, Samuel Hatton, John Parker; and Henry Wheeler, whose depredations have extended to thirty Burial Grounds that the informant knows of; and that grave diggers, and those intrusted with the care of Burial Grounds, are frequently accessory to the robberies, and receive five shillings per Corpse for every one, that with their privily is carried off, by which means many hundreds are taken from their graves annually.

"That with the Surgeons and with the men above alluded to, there is a set price for dead bodies, Viz. for an Adult, two guineas and a Crown, and for every one under age, six shillings for the first foot, and nine per inch for all it measures more in length; that the bodies thus procured are used here in various ways, and the flesh by some burnt, by others buried, and by others the informant did not know how it was disposed of; that some bodies are prepared and made into Skeletons, and sent to America, and the West Indies; and many with the flesh on, or made into Skeletons, are sent into different parts of the Kingdom.

"By another informant upon oath, the whole of which was also now read, it appeared that the aforesaid Articulator, makes the most wanton use of some that fall into his hands, substituting human skulls for nail boxes, and having the Skeleton of a Child, instead of a doll, for his own child to play with.

"The Chairman also acquainted the meeting, that from other evidence (which though not yet upon Oath yet such as may be relied on) information is given that experiments have been tried and perfected, whereby human flesh has been converted into a substance like Spermaceti, and candles made of it, and that Soap has also been made of the same material."

The representatives of the various London parishes who attended the meeting were indignant at the state of the law over body-snatching, and a subsequent meeting decided to try to get a Bill passed to make the stealing of bodies a capital offence. St. Thomas's vestry decided to subscribe five guineas to the expenses of such a Bill.[7]

LAURENCE DOPSON.

The licensing of foreign medical graduates in the United States has recently been discussed by Barker and Mooney in the *Journal of the American Medical Association* (1949, 140. 10). Twenty-three States will not admit graduates of any schools outside the United States and Canada. At the time of writing there were eight States in which recent graduates of foreign medical schools may be permitted to practise. In addition, graduates of certain schools in Great Britain may be acceptable in several other States. It appears that two States, Mississipi and Rhode Island, admit foreign graduates without much restriction. The rules made by the various State examining boards change rapidly, and it is difficult to provide completely reliable and up-to-date information.

ONE HUNDRED AND SEVENTEENTH ANNUAL MEETING

of the

British Medical Association

HELD AT HARROGATE, JUNE, 1949

THE SECTIONS

SUMMARY OF PROCEEDINGS

In subsequent issues there will be printed in the BRITISH MEDICAL JOURNAL *a few of the opening papers read at the Scientific Sections. All the papers will be published in full in a separate volume of Proceedings. The reports of the discussions in this and successive issues are intended to give members who were not present a general idea of the proceedings.*

SECTION OF MEDICINE

Tuesday, June 28

Diabetes Mellitus

After Professor R. E. TUNBRIDGE (Leeds), president, had opened the meeting, Professor A. P. THOMSON (Birmingham) took the chair, and Dr. R. D. LAWRENCE (London) opened a discussion on diabetes mellitus. He said that recent experiments, especially with tracer elements, had shown that a large amount of the excess of carbohydrate taken into the body was rapidly changed into and stored as depot fat. Chemical metabolism was dependent on enzyme actions, accelerated or retarded by hormone influences; glucose was unavailable until it had been changed into phosphate compounds. Insulin stimulated the enzyme hexokinase, which formed hexase phosphate; after that, other enzyme systems took on further processes in carbohydrate utilization. Insulin thus made an excess of glucose available by phosphorylation, first for immediate burning, secondly for a glycogen store, and thirdly and largely for storage as fat.

Diabetes might be divided into two types—they might even be two distinct diseases. There was the middle-aged obese person, particularly women at the menopause, in whom the urine was laden with sugar but there was no ketosis. That type should rightly be treated by diet alone, a diet low in carbohydrate, fat, and calories, with the aim of reducing weight. When those patients had lost weight the sugar disappeared. The use of insulin was bad, for it tended to continue and even increase the obesity, which was the essential defect. The second type, with wasting and ketosis, occurred mostly in young adults, and the presence of ketosis indicated a real deficiency in insulin production requiring substitution injections. Thus the test for ketones was of the greatest importance.

There were now several types of insulin (see Table). Their difference in time and strength must be clearly appreciated for their efficient use in treatment. Dosage must be regulated by trial and error; there was no individual dose.

There were two groups of the type of diabetic who needed insulin. The severe diabetic produced no endogenous insulin, responded rapidly for some hours while insulin absorption was strong, but relapsed into a severe diabetic state when absorption ended. There was also the milder group of patients who produced some endogenous insulin but who needed some exogenous insulin after eating a reasonable amount of carbohydrate.

Professor R. E. TUNBRIDGE (Leeds) said that experimentalists had shown that in diabetes in animals, produced by partial pancreatectomy or alloxan, a limitation of calorie intake slowed the rate of development of hyperglycaemia and ketosis, and statisticians had shown that there had been a decline in mortality from diabetes mellitus after the introduction of rationing during both world wars. It seemed that calorie restriction was essential in constructing a diabetic diet. He suggested the following as being reasonable diets: (1) For the obese, a period on a diet of 1,000 to 1,500 calories; (2) for the elderly, a diet of 1,200 to 1,800 calories; (3) for the remainder of the diabetics, a calorie value of 1,800 to 2,400. Only a small percentage of patients actually took the diets prescribed. Of 94 patients attending the Leeds General Infirmary who recorded their food intake for one complete week in March, 1948, together with its cost and other relevant sociological factors, 16 yielded satisfactory results; in 44 the findings were tolerably satisfactory, and in 34 hopeless. The causes were (1) lack of intelligence and inadequate training; (2) economic; and (3) sociological. Unfortunately the intelligence quota of many out-patients was such that it was almost impossible to teach them the intelligent use of equivalents. The economic factor was usually overlooked. The survey showed that the cost to the average diabetic patient was at least 25s. per week (compared with an average of 10s. per week for non-diabetic diet), and only in one or two instances had it been possible for a person to maintain an adequate diet at a lower cost.

Insulin in Adults

Type of Insulin	In Doses	Duration of Action	Commonest Time of Hypoglycaemia	Remarks on Type of Action
Soluble	to 10 units to 20 ,, to 40 ,, +	5–6 hours 6–8 ,, 10–12 with big doses	2–4 hours 3–6 ,, 6–8 ,,	Begins action within ½ hour Quick and strong Balances much carbohydrate
Protamine zinc insulin	to 10 units to 20 ,, to 30 ,, 40 units +	6–8 hours to 12–18 hours to 18–24 ,, 24 hours or longer	5 hours 8–12 hours 8–20 ,, 16–24 ,,	Begins action within 3 hours Action weak but prolonged Balances carbohydrate poorly
Delay (retard) and globin zinc insulin	to 20 units to 40 ,, + to 60–100 units +	8–10 hours 12–16 ,, 24+ ,,	5–8 hours 9–10 ,, 10–24 ,,	Much nearer soluble insulin in action than to P.Z. insulin

Mr. D. A. HALL, Ph.D. (Leeds), described a method of estimating the blood sugar—a micro-colorimetric method repeatable with great accuracy, quick, simple, requiring little apparatus, and with durable reagents. Blood, 0.1 ml., was washed into 3.7 ml. of isotonic copper and sodium sulphate solution (320 ml. of 3% $Na_2SO_4.12H_2O$, 30 ml. of 7% $CuSO_4.5H_2O$). The protein was precipitated by 4 drops of 4% sodium tungstate. The mixture was then shaken and filtered through fluted paper into a tube graduated at 1, 1.5, 2, and 5 ml. 1 ml. was collected; Solution A (1.3% $CuSO_4.5H_2O$) was added to 1.5 ml., and then Solution B (24% sodium potassium tartrate, 4% Na_2CO_3, 5% $NaHCO_3$, 3.68% potassium oxalate, 0.14% KI). The tube was plugged with cotton-wool and boiled for 10 minutes. After cooling, phosphomolybdate solution of Folin and Wu (1920) was added to the 5 ml. mark. The colour was then compared with standards.

Dr. A. J. BALLANTYNE (Glasgow) described the ocular changes in diabetes, and said that the late stage was not often seen because of cataracts, vitreous opacities, and haemorrhages, but the disk became obliterated by infiltration and oedema, and there was gross infiltration throughout the fundus. There was no cure for diabetic retinopathy.

Mr. H. H. FOURACRE BARNS (London) said that pregnancy complicated by diabetes mellitus was associated with a high mortality rate. Despite the introduction of insulin the foetal mortality rate had remained at approximately 40%. Large babies and a high foetal mortality rate occurred also in the case of women who subsequently developed diabetes. It had been thought that overactivity of the maternal anterior pituitary gland might be responsible. A series of diabetic pregnant women had therefore been treated with 35–40 mg. stilboestrol

daily; so far 16 had been treated, with four neonatal deaths. There had been no reduction of the tendency to produce large infants, which would suggest that either their hypothesis of the diabetogenic growth complex causing gigantism was incorrect or stilboestrol in the dosage given was not effective in suppressing the production of that hormone.

Dr. CHARLES ROLLAND (Edinburgh) thought it possible that overactivity of the anterior lobe of the pituitary might be the common cause of diabetes, large foetus, and pre-eclamptic toxaemia.

Dr. R. G. PALEY (Leeds) said that cutaneous reactions occurred in 55.8% of patients. They were due to impurities in the insulin and could be greatly reduced by using six-times recrystallized insulin solution. In 30% of patients there was a spontaneous desensitization, and in the rest the symptoms were rarely severe enough to indicate the purified insulin. Dr. K. M. A. PERRY (London) remarked that 1 in 40 diabetics developed pulmonary tuberculosis, and therefore it was essential to examine their chests by *x* rays at frequent intervals. Dr. R. R. BOMFORD (London) emphasized that growing adolescents were the exception to the rule of dietary restriction. They must have enough food to grow.

Dr. ELLIOT P. JOSLIN (Boston, U.S.A.), described by the chairman as the "grand old man" of diabetes and as essentially a general physician, discussed the changes in treatment that had taken place in his lifetime. He had treated diabetes for 25 years before insulin; now diabetic coma had almost disappeared. Diabetes was commoner than generally believed. In his home town the U.S. Public Health Service had carried out a survey of the 5,000 inhabitants, and besides the 40 known diabetics they had found 30 more unknown ones. The doctor treating diabetes who maintained a strict control over his patients had great opportunities for studying disease and learning of its beginnings. Of the 229 deaths which had occurred in his diabetic patients only 5 had resulted from the diabetes. Diabetes was universal; it was as common in rich towns as in poor towns. It was as common in the Red Indian as in the negro and white populations. In the 150 millions in the United States there were one million known diabetics and probably as many unknown.

SECTION OF OBSTETRICS AND GYNAECOLOGY

Tuesday, June 28

Breech Presentation and its Management

Mr. R. NEWTON (Manchester) said that many statistics on breech presentation and its management had been produced since the Annual Meeting at Belfast in 1937, when Macafee and McClure surveyed a series of 349 breech deliveries, with a corrected foetal mortality in primiparae of 10%, in multiparae of 3.42%, and in all cases of 6.10%. Potter, of Buffalo, had fired the imagination with his good results, and at the B.M.A. meeting at Eastbourne in 1931 Holland, Gibberd, and Bourne had pointed out the heavy loss of foetal life in breech deliveries. Since 1931 external version had come to be accepted by nearly all authorities. Keith Vartan had shown that by the thirty-fourth week most cases had undergone spontaneous version and that few would undergo reversion. The reversion rate was higher after external version, "a fact which suggests that the obstetrician is not so clever as the foetus in deciding when the operation should be done." External version was best accomplished by pushing on one pole of the foetus and turning the easiest way. At Withington Hospital, Manchester, he had found that there was a foetal mortality of 2.6% in 116 successful versions. If version failed, the obstetrician's first duty was to exclude the possibility of contracted pelvis.

The first stage of a breech delivery could be managed in much the same way as a normal vertex presentation. There was greater likelihood of prolapse of the cord when the membranes ruptured. Several authors—for example, Heaton and Guyer—had shown that early rupture of the membranes, which was more common in breech deliveries, did not contribute to foetal mortality. Difficulties arose in the second stage of labour. Sir Eardley Holland had emphasized that the foetus died of trauma, always or nearly always—and nearly always at the outlet. Other causes of death were not important.

Mr. Newton stressed the need for attention to detail. He practised conservative methods of delivery, but when difficulty arose he undertook complete extraction under general anaesthesia. This presupposed a trained anaesthetist. Episiotomy, he thought, was nearly a necessity in every primipara, but he preferred conservatism and the insertion of a stitch as soon as the perineum showed signs of tearing. It was seldom that the tear extended when this was done. For the arms he used Potter's or Lövset's method; for the head, the Mauriceau grip, but forceps always in difficult cases.

The speaker went on to analyse 12 years' booked cases at St. Mary's Hospital, Manchester. They showed a corrected foetal mortality of 7.1%.

Foetal Mortality

Total Number of Cases	Caesarean Section	Remainder	Gross Foetal Mortality	Corrected Foetal Mortality			
				Twins Included	Second Twins Excluded	First Twins Excluded	Prolapsed Cord Excluded
1,148	147	1,001	26·5%	6·6%	6·8%	7·3%	6·1%
Corrected to 5½ lb. (2·5 kg.)				6·8%	7·4%	7·9%	6·5%

Foetal Mortality Rates in Primiparae and Multiparae

	Gross Foetal Mortality	Twins Included	Second Twins Excluded	First Twins Excluded	Prolapsed Cord Excluded
Primiparae ..	21·5%	6·7%	7·1%	7·4%	6·5%
Multiparae ..	34%	6%	6·2%	6·9%	5·1%
Corrected to 5½ lb. (2·5 kg.) ..					
Primiparae ..		7·3%	7·5%	7·5%	7·5%
Multiparae ..		6·2%	7·3%	8·7%	6·5%

The corrected foetal mortality for the last five years was as follows:

Weight	Corrected Foetal Mortality
From 3–4 lb. (1·4–1·8 kg.) ..	40%
4–5 lb. (1·8–2·3 kg.) ..	28%
5–6 lb. (2·3–2·7 kg.) ..	3%
6–7 lb (2·7–3·2 kg.) ..	6%
7–8 lb. (3·2–3·6 kg.) ..	4·5%
Over 8 lb. (3·6 kg.) ..	24%

By treating contracted pelvis, large babies, or prolonged labour by caesarean section, more babies could have been saved. There remained a hard core of "unexplained" foetal deaths, as well as those with prolapse of the cord. The answer to this was supervision by a team of experienced obstetricians and probably the more common use of breech extraction.

Dr. J. LÖVSET (Bergen) was welcomed as a distinguished visitor responsible for a marked advance in the treatment of breech presentation. He reviewed the conditions of practice in Norway. He stated that in breech deliveries he did not interfere before the buttocks were born if labour was proceeding normally. He considered that there were three indications for bringing down a leg: (1) mechanical disproportion (compound presentation or extended legs); (2) functional dystocia when incision of the cervix might be required at the same time that the leg was brought down; (3) signs of distress in the mother or foetus. Which leg was brought down was unimportant.

Dr. Lövset's material comprised breech deliveries over the last 14 years at the Hospital for Women in Bergen. During the first seven years the deliveries were managed conservatively, whereas during 1941–7 they were treated as he had previously indicated. Twins, versions, and extractions were excluded. The corrected foetal mortality rate for 1934–40 was 9.86% and for 1940–7 3.93%. He advised a careful watch during labour and delivery, and the prophylactic bringing down of the leg.

Mr. B. L. JEAFFRESON (Leeds) considered only primigravidae. He said that the factors favouring successful delivery were as follows. (1) A small child. Labour should be induced if there was evidence that the child was likely to be larger than one weighing 7 lb. (3.2 kg.) (2) A pelvis of normal size and shape. In all cases this should be investigated by internal palpation or by x-ray pelvimetry before labour started. (3) Relaxation of the pelvic floor and vulval orifice. It was possible that this could be obtained by the exercises advocated by Grantly Dick Read (see *Journal*, April 16, p. 651). (4) Adequate experience on the part of the obstetrician. (5) Deep surgical anaesthesia. The practice of the same doctor anaesthetizing the patient and conducting the delivery was to be condemned. Caesarean section was to be considered only when the patient was elderly or the delivery was made difficult by some other obstetric complication.

Mr. C. MCINTOSH MARSHALL (Liverpool) said that the foetal mortality in breech delivery was primarily and finally dependent more upon the weight—that is, the size—of the infant than upon any other single factor. He produced figures, which are shortly to be published, in support of this thesis. Three general rules could be disregarded only at the expense of foetal lives: (1) There should be no vaginal breech delivery, whatever the weight of the infant, through an abnormal or contracted pelvis. (2) There should be no vaginal delivery of an infant over 7 lb. (3.2 kg.) through a "borderline" pelvis. (3) There should be no vaginal delivery through a normal pelvis if the weight of the infant was estimated to be over 9 lb. (4.1 kg.). These rules may be relaxed slightly in the case of multigravidae.

Mr. Marshall analysed 686 breech deliveries in 10 years. There were 27 foetal deaths—a mortality rate of 3.94%. And to show that progress was being made, in the last five years there were 374 deliveries with a mortality rate of 3.21%.

Professor A. M. CLAYE, who presided, opened the discussion by questioning Mr. Marshall's choice of different weight categories. He found it difficult to judge the weight of the foetus *in utero*. Mr. T. F. REDMAN (Manchester) said there was little justification for claiming that foetal losses in breech delivery could be reduced to the losses in vertex delivery. Certain factors—for example, prolapsed cord and difficulty at the brim—could be circumvented only by avoiding breech presentation. He believed, and produced evidence to show, that these factors operated as frequently in multigravidae as in primigravidae. Consequently, multiparae should receive just as much obstetrical care as primigravidae. All breech presentations should be delivered in hospital under responsible supervision.

Others taking part in the discussion were Mr. A. L. GUNN (London), Dame LOUISE MCILROY (London), Dr. ALAN BARKER (East Kent), Mr. G. GORDON LENNON (Oxford), and Dr. S. L. NAVARATNAM (Colombo).

Dr. LÖVSET in reply said he had never seen prolapse of the cord after bringing down a leg. He showed a film of the Lövset method of dealing with the shoulders. Mr. MARSHALL showed two films of breech delivery, and Mr. NEWTON summed up the discussion.

SECTION OF PATHOLOGY AND BACTERIOLOGY

Tuesday, June 28

Laboratory Diagnosis and Prevention of Whooping-cough

Professor ROBERT CRUICKSHANK (London) pointed out that whooping-cough was to-day the most serious of the specific fevers of childhood. It attacked some 70% of children and was an infection of early life with two-thirds of the cases in pre-school children and more than half the deaths in the first year of life. It was generally accepted that the infection was caused by *Haemophilus pertussis*, which could be cultivated from nasopharyngeal swabs or bronchial secretion on Bordet-Gengou medium.

Methods of controlling spread of the infection might be by early diagnosis and isolation of the primary case in nursery or family; by passive protection of contacts with specific antiserum; and by active immunization of susceptible children with pertussis vaccine. Because early clinical diagnosis was difficult when the child was most infectious, and because the cough-plate method was not easily carried out in domiciliary practice, they had used either swabs passed through the mouth to the postnasal space (postnasal swab) or fine swabs on flexible wire passed through the nose (pernasal swab). The latter method, used on infants between 6 and 18 months of age, had given a higher proportion of positive results and more profuse growth, practically free of contaminants, compared with the postnasal swab taken from the same infants at the same time. As an example of the value of these bacteriological methods of diagnosis, in the practice of one doctor swabs or cough-plates from children with suspicious coughs had in one year yielded positive cultures in 24 out of 36 cases subsequently confirmed clinically as pertussis; 23 of the positive results came from 24 early doubtful cases.

The demonstration of specific antibody by complement fixation or agglutination reactions was of no value for early diagnosis, as the antibody developed late in the infection, but a positive result could be used to confirm a dubious clinical history up to four to six months after the onset.

Early bacteriological diagnosis of a primary case in day or residential nurseries allowed the effective use of specific antiserum, prepared in horses or rabbits, for the passive protection of susceptible contacts. In three outbreaks antiserum had been given to half of the susceptible contacts, and the results indicated that the serum gave temporary protection if injected during the incubation period. Because of the risk of reactions to a foreign protein, hyperimmune serum, prepared by the immunization of adult donors, had been used, apparently with success, by American workers both for prophylaxis and for treatment. As the dose was 20 ml. repeated once or twice, it seemed a logical step to fractionate such hyperimmune serum and use the concentrated antibody-containing globulin.

At first sight active immunization against whooping-cough seemed to present little difficulty, since the infecting organisms were all serologically of one type and the clinical infection resulted in a high degree of immunity. Early experience with pertussis vaccines, before it was realized that smooth (phase I) virulent strains must be used, was disappointing, but even more recently different trials in America had given discrepant results, and a controlled trial among nursery children with a British vaccine had failed to show any protection. Obviously, with the increasing interest in the prophylactic use of pertussis vaccine, it became desirable to carry out controlled field trials with vaccines prepared in different ways to find out if any vaccine gave sufficient protection to justify its large-scale use and, if so, what were the essential requirements in a good vaccine. A committee of the Medical Research Council had been attempting to find the answers to these questions during the past few years.

Dr. W. C. COCKBURN (London) described the organization of the M.R.C. trials which were being carried out in eight different areas throughout the country. Only infants between the ages of 6 and 18 months, now totalling some 16,000, had been accepted, and every effort had been made to keep the vaccinated and control groups strictly comparable. Analysis of data on age, sex, size of family, feeding history, and previous infections other than pertussis showed that the two groups were remarkably alike. Workers engaged in the trials did not know which children had received the pertussis vaccine and which the control material. There was a very careful follow-up period of at least two years, with laboratory confirmation of suspicious cases.

Dr. D. G. EVANS (Manchester) pointed out that the antigenic structure of *H. pertussis* was complex. At least four antigens had been detected in phase I strains—agglutinogen, toxin, haemagglutinin, and soluble capsular substance. The importance of any one of these antigens in prophylaxis was not yet clear, and their protective value could be determined only by clinical trial. It was possible, however, from laboratory experiments to obtain some evidence of the relative importance of different antigens. Mice, which could be infected either intranasally or intracerebrally with *H. pertussis*, were being used to investigate the prophylactic effect of different antigens and their respective antibodies. Such investigations might reveal the effective immunizing antigen, or antigens, and allow the production of vaccines of more certain prophylactic potency than

was possible at present. They might also lead to the use of a purified bacterial fraction instead of the whole bacterial body.

In the general discussion, Dr. B. W. LACEY (London) said he had been using pernasal and postnasal swabs for the diagnosis of pertussis in children with suspicious coughs. From some 450 children he had isolated *H. pertussis* in over 100 cases and *H. parapertussis* in 14 cases. In four of the latter group *H. pertussis* was also present. He described the distinctive features of *H. parapertussis*, which could be isolated selectively by incorporating 5 units of streptomycin and 1 unit of penicillin per ml. of Bordet-Gengou medium. The organism was associated with a rather mild infection, usually occurring in small family groups.

Dr. H. SUGARÉ (Leeds), speaking as a general practitioner, stressed the urgent need for an effective prophylactic against this serious and debilitating disease. Dr. J. UNGAR (London) said that he had found 48-hour cultures most virulent for mice, but could not demonstrate a close correlation between mouse virulence and the haemagglutinating fraction of the organism.

In summing up, Professor CRUICKSHANK hoped that practitioners would soon be using the pernasal swab for the diagnosis of suspicious coughs in the same way as they used the throat swab for the differential diagnosis of sore throat.

Care and Treatment of Laboratory Animals

Dr. JEAN VINTER (London), technical secretary to the Universities Federation for Animal Welfare (UFAW), said that the welfare of laboratory animals depended on the good will of the experimenter and his technical assistants, on a sound knowledge of animal husbandry, and on the control imposed by law, in that order of importance. Legal control limited experimentation on animals to *bona fide* scientific purposes, required licensing of the experimenter and the premises, and instituted unannounced inspection by Home Office inspectors. There was legal control of animal experimentation in very few other countries and, as the British law was cumbersome, she had thought of drafting a model law with the inspector as a friendly adviser on animal care and outlining the conditions under which research work on animals was best performed.

Such a model law might be based on a schedule of degrees of suffering rather than on favoured animals, since there was no evidence that rats or mice suffered pain any less than cats or dogs. There should also be a qualified veterinary adviser attached to the Home Office inspectorate, who could be consulted about the breeding and supply of laboratory animals, their care and maintenance, the choice of anaesthesia, etc. It was worth while studying the *UFAW Handbook* and keeping in mind such points as these: needles should be really sharp; animals should have adequate space for exercise; most animals in captivity required water to drink; the best methods of anaesthesia should be known and practised; and there should be the same care and forethought given to the planning of animal as to the planning of test-tube experiments. It would be useful, too, if all medical students were required to attend one lecture on the functions and scope of animal experimentation in medical research.

Professor ALASTAIR N. WORDEN, editor of the *UFAW Handbook*, commented on the quickening of interest and recent progress in the use of small animals for biological research. He mentioned particularly the setting up of the Laboratory Animals Bureau by the Medical Research Council; studies on animal breeding and feeding at the National Institute for Medical Research, Hampstead; and the publication of the *UFAW Handbook*. He stressed the need for better standards in the training and status of animal attendants; the use of suitable food-containers to avoid wastage; the need for supplies of homogeneous stock; and the steps to be taken to avoid natural parasitic, bacterial, and virus infections among laboratory animals.

Professor R. J. V. PULVERTAFT felt that strong representations should be made to hospital management committees and other lay hospital bodies on the requirements for the proper housing and care of laboratory animals. Professor G. P. CROWDEN (London) said that more attention should be given to environmental conditions—heating, lighting, ventilation, and relative humidity—in animal houses.

SECTION OF RADIOLOGY

Tuesday, June 28

Scope and Limitations of Radiotherapy

Dr. J. S. FULTON (Liverpool) said that the action of radiation in the *x* and gamma ranges was fundamentally damaging. The effect of the dosage depended upon the volume of tissue irradiated. This concept enabled the effect of small doses in inflammatory conditions or of large doses in malignant disease to be assessed. A more favourable response was usually obtained when the treatment was in a relatively vascular area; it was less good when the vascular supply was temporarily impaired. Patients with carcinoma of the tongue who had syphilis or had had it previously, for example, invariably responded less favourably. Carcinoma of the lung, which appeared to be on the increase, offered a field in which radiotherapy was of real value, although it could rarely be regarded as other than palliative. The relief from pain and dyspnoea which radiation afforded was a genuine contribution to the treatment of the condition. Carcinoma of the oesophagus, again, was another valuable field for radiotherapy, and the same applied to radio-sensitive tumours of the nasal accessory sinuses.

There was a tendency to regard tumours of bone as hopeless, but this view was frequently unjustifiable, and he instanced cases in which good results had followed radiotherapy. In the treatment of non-malignant conditions he had obtained consistently good results in plantar verruca. The value of radiotherapy in ankylosing spondylitis and arthritic conditions was well established.

Dr. CHESTER WILLIAMS (Bradford) discussed treatment by radiotherapy in four anatomical sites. In the skin, radiotherapy had achieved its greatest success in the treatment of accessible tissues, but the more experienced the dermatologist the more conservative he was in its use. A dermatological colleague had come to the conclusion that it should not be used to treat lesions of the palm of the hand or the sole of the foot. Sufferers from pruritus ani needed urgent relief, which could be given in many cases by radiotherapy. Over 90% of rodent ulcers were treated successfully, but there were limitations in the treatment of epitheliomata—for example, radiotherapy was not successful in the treatment of epithelioma of the dorsum of the hand in the elderly. Lesions in the mouth, whether malignant or non-malignant, responded well to radiotherapy. In cancer of the breast he believed that simple mastectomy and radiotherapy was the treatment of choice. In cases of recurrent and metastatic cancer isolated nodules could be treated and would remain isolated for years, but multiple skin nodules presented an almost insoluble problem. Radiation could be repeated too often; plantar warts should be treated once only. There were also long-term dangers in treating excessive hair growth.

In some general discussion Professor B. W. WINDEYER said that radiotherapy must be regarded as a dangerous method of treatment, not to be used when other simpler and less dangerous methods would be effective. With regard to the treatment of ankylosing spondylitis, if the radiation was given through the sacral joints sterilization was apt to follow, but he thought it was possible to apply the radiation tangentially through those joints in such a way as to avoid this sequel.

Dr. J. R. NUTTALL (Leeds) said that in cases of carcinoma of the prostate he had used a combined method of orchidectomy, stilboestrol, and radical *x*-ray therapy; quite a number of patients were alive and well after four or five years. Dr. C. G. HITCHCOCK (Harrogate) said that sometimes children were seen with warts very widely distributed over the body; if the main groups were treated the whole body was freed. Dr. FULTON said that this was a well-authenticated phenomenon. Warts were contagious, and by taking a careful history the mother wart could be located; if it was treated radically all the warts would disappear.

A question was raised on the use of *x* rays in treating strawberry naevi. Dr. CHESTER WILLIAMS said that he had tried to persuade mothers who had children with this disfigurement to leave it, at least until the children had to go to school; but if the naevi did not disappear spontaneously it was a very slow process. Dr. FULTON said that the worst possible thing was the application of carbon-dioxide snow.

SECTION OF SURGERY

Tuesday, June 28

Prostatic Obstruction

With the president, Mr. T. V. PEARCE (Harrogate), in the chair, Mr. H. HAMILTON STEWART (Bradford) opened the discussion by a consideration of 2,192 patients treated in hospital and private practice. The safest course for the general practitioner was to dispatch the patient suffering from acute prostatic retention to hospital. The dangers of attempting catheterization were trauma, infection, the effects of rapid decompression, and failed catheterization, but if instrumentation was performed these could be offset by a careful technique. An initial injection of 10 ml. of sterile water-soluble lubricant into the urethra was given. The catheter, its end clipped to lock the air in its lumen, was then introduced through a meatus controlled by compression of the glans. This procedure allowed a hydraulic column to advance ahead of the catheter and prevent damage to the mucosa. Catheterization should never be repeated. Suprapubic aspiration, the alternative to catheterization, carried the risk of damage to an intraperitoneal dome. "Silent retention" was easily overlooked if the bladder dome was intraperitoneal; to detect it, bimanual examination was invaluable, with ballottement of the bladder between a hand on the abdomen and a finger in the rectum. Diagnostic catheterization was dangerous, and unnecessary unless urethral stricture coexisted. In general, prostatectomy was desirable as soon as the diagnosis was established, unless coincident disease made the expectation of life short. Only if obstruction was slight and residual urine was small in amount might the patient be treated conservatively—and watchfully. Indwelling catheters required special care; the instrument should not be too large, and leakage of mucus around it should be encouraged by careful and repeated removal of the meatal crust of dried discharge. The presence of a congenital stricture of the urethra called for special care; tight meatal strictures called for meatotomy, higher strictures for transurethral prostatectomy by the perineal route.

It was a mistake to use one method of prostatectomy to the exclusion of all others. In 1,347 perurethral operations, performed with the use of the Thomson punch, the mortality had been 3.04% even though most of the bad-risk cases were included. If properly performed this procedure allowed as thorough a removal as any other and there was no greater risk of recurrence. Open operation, in one or two stages, and chiefly by the transvesical route, had been performed in 613 cases, with a mortality of 2.93%. The one-stage operation had been used in an increasing proportion, and in the last five years had been used in 70.9% of the patients treated by open operation, with virtually the same mortality as was obtained in the 16% of patients so treated in the previous five years. The main indications for the open operation were (1) the concurrence of prostatic obstruction with cancer, diverticulum, or stones in the bladder, or with congenital or acquired stricture of the urethra, and (2) large prostates weighing more than 70 g. Multiple resections were to be avoided except when the only alternative was a permanent suprapubic tube. For carcinoma of the prostate large doses of oestrogen were indicated, obstruction being relieved by transurethral wedge-resection.

Mr. WILSON HEY (Manchester) concluded from the fine results recorded in the previous paper that cases of enlarged prostate should go to the specialist and not to the general surgeon. In the preparation for operation penicillin and, if possible, streptomycin were preferable to sulphonamides. Particularly, these drugs must be given before and after catheterization. If catheterization must be performed (and suprapubic puncture was preferable) then prostatectomy should follow in 48 hours. Malignancy after removal of an apparently benign prostate was a special danger now that the survival period after prostatectomy was increasing. Subcapsular orchidectomy followed by minimal doses of oestrogen was employed in combination with prostatectomy whenever cancer was suspected.

Mr. ASHTON MILLER (Bristol) argued in favour of the retropubic operation. He supported the previous speakers in their advocacy of early prostatectomy and, in acute retention, immediate prostatectomy. Where immediate prostatectomy was inadvisable, low suprapubic puncture was preferred to catheterization. Diagnostic catheterization of patients not yet in acute retention was not now desirable. The desire to micturate after naturally emptying of the bladder was a better index of a high residual urine. Intravenous cystography immediately after natural micturition gave an even more precise measure of the residual urine. The transurethral operation was difficult, and in the hands of the inexpert dangerous, though its efficiency in expert hands was admitted. Transurethral resection was reserved for the small adenomatous or fibrous prostate. The only satisfactory method of distinguishing between adenomatous and fibrous obstruction was cystoscopy, or preferably cysto-urethroscopy. The retropubic operation gave, in his hands, better results than any other, though probably no one method should be used exclusively. Only in a few cases, particularly of small fibrous glands, was the operation difficult. Infection and secondary haemorrhage were particularly troublesome in patients with chronic retention, but even in these the retropubic technique was more satisfactory than any form of two-stage operation.

Mr. JOHN SWINNEY (Newcastle-upon-Tyne) attached particular importance to the character of the stream of urine observed when the patient micturated before him. Rectal examination provided little information of the total size of the enlarged gland and must be supplemented by cysto-urethroscopy. Cystoscopy should be followed at once by operation in cases when it provided a clear diagnosis of obstruction. The amount of residual urine was considered an unreliable guide to the bladder condition; against it must be considered the degree of tone in vesical and sphincteric muscle.

Transurethral resection was limited to glands of less than 100 g. weight—the maximum amount of tissue which could be removed in an hour. Bulky upward enlargement lent itself to the transvesical operation, bulky lateral and posterior enlargements to the retropubic. The total mortality rate was 4 to 5% in any year. The lower rate (1–2%) reported in the United States could not be easily explained; the speaker, using the same technique in both countries had obtained a substantially lower mortality rate in America than he had subsequently obtained in England. Perhaps the explanation was that in the former country patients, more prostate-conscious, came to the surgeon earlier.

In the subsequent discussion introduced by Mr. IAN FRASER (Belfast), vice-president of the Section, Mr. THOMAS MOORE (Manchester) pointed out that the transurethral procedure, often advantageous as it might be, was a serious operation if adequately performed. In his experience the retropubic operation was of less magnitude and, on the whole, better sustained by the patient. Mr. R. MARCUS (Liverpool) urged that streptomycin be reserved for use against the rare pyelonephritis after operation; if given before operation streptomycin-resistance might occur.

Replying, Mr. HAMILTON STEWART emphasized the importance of meticulous haemostasis in preventing post-operative haemorrhage; serious haemorrhage could not be controlled by catheter lavage. In the detection of malignant disease a positive diagnosis by either clinician or pathologist should stand against a negative diagnosis by the other. In the treatment of cancer of the prostate, castration and oestrogen therapy were preferable in the first instance, to be followed by deep *x*-ray therapy if symptoms returned or if the histological pattern of the tumour changed, as it sometimes did. Mr. WILSON HEY, replying to questions, said he preferred the vertical incision when malignant disease was suspected, because of the greater access it afforded, and the transverse suprapubic incision in other cases. Haemostasis depended on accurate use of the endotherm apparatus. The transvesical approach seemed preferable to others because of the wide visual access which it afforded. In the treatment of suspected prostatic cancer wide resection of prostate and seminal vesicles was a prerequisite, even if it put the rectum to a little hazard, or if it entailed opening the peritoneum; carcinoma sometimes developed, after prostatectomy, in the seminal vesicles.

SECTION OF ANATOMY AND PHYSIOLOGY

Tuesday, June 28

Control of Activity in the Gastro-intestinal Tract

Professor R. A. GREGORY (Liverpool) gave an account of experimental work designed to determine the nature of the mechanisms controlling intestinal tone and motility after meals in relation to the passage of food along the intestine. Observations had been made on unanaesthetized dogs with two Thiry-Vella loops in the mid-part of the small intestine. Fluid was fed into the loop from a reservoir and the rate of passage of fluid and the associated intestinal contractions could be recorded; the method was more sensitive than those employing balloons in the lumen of the gut. It measured the resistance to the flow of liquid and the general nature of the motility elicited in the loop. A general diminution in tone was associated with a rapid flow and a decrease in rhythmic contractions. After a prolonged fast the loop was in a "basal" state on which there were superimposed some alternating periods of quiescence and activity. When a meal was given there were almost immediate changes with slowing of the flow and an increase in motility. The effect of a meal might last for several hours, though in diminishing degree.

Analysis showed that the response was nervous and was mediated through the vagus with two probable sites of origin, (*a*) cephalic reflex stimulation, and (*b*) distension of the stomach. If the animal was "sham-fed" the typical response occurred even though the food had not entered the stomach. Alternatively the response appeared if the stomach was distended by a balloon or if the mucosa was stimulated gently by a blunt instrument inserted through a fistula. The reaction did not occur if the loop was denervated, but was gradually restored as regeneration took place.

The effect of alterations in the chemical composition of the fluid perfusing the gut had also been studied. The addition of bile salts, protein digestion products, or hypertonic saline retarded or stopped the flow, and the contractions of the loop were increased so that the fluid tended to reflux to and fro between the loop and the reservoir. Increase in acidity of the fluid slowed the flow until some neutralization had been effected. It was thought that there were local reflex arcs in the wall of the intestine, because the response to chemical changes was abolished by applying a local analgesic to the mucosa.

Dr. J.-J. SPIRA (London) held that the peristaltic wave was the most important means of intestinal propulsion, and that there was no evidence of a physiological mechanism to produce retroperistalsis. The sphincters might operate to prevent retrograde movement of the intestinal contents.

Dr. J. N. HUNT (London) described work undertaken at Guy's Hospital on the rate of emptying of the stomach. Existing techniques for test meals did not allow a complete picture of the emptying pattern to be built up, but by giving serial test meals to an accustomed subject on successive days and withdrawing specimens after different periods it was possible to construct charts which would show, for any instant, the volume of the original meal remaining in the stomach, the volume of the gastric contents, and the rate at which the gastric contents were leaving by the pylorus. The meal, which was physiologically inert, contained pectin, sucrose, phenol red, and NaOH to adjust to *p*H 6.5. The amount of dye remaining in the stomach could be calculated, and therefore the rate at which the meal was passing through the pylorus.

The pattern of emptying had been found to be much more regular and fixed than had been expected. In 21 subjects the mean rate of emptying was 3% of the gastric contents per minute—the rate of emptying varying with the volume of the gastric contents, provided the stomach contained between 20 and 750 ml. of standard meal. About half the contents passed out every 22 minutes.

Dr. A. A. HARPER (Manchester) surveyed the development of knowledge about the regulation of gastric and pancreatic secretion. He had confirmed Mellanby's findings that secretin caused a copious flow of enzyme-free pancreatic juice and that stimulation of the vagus led to the appearance of a small volume of secretion rich in enzymes. Even when all nervous connexions had been cut the passage of a meal from the stomach was followed by a large secretion of pancreatic juice containing enzymes. Working with Professor Raper, he had isolated pancreozymin, a hormone which caused enzyme secretion. This action was not affected by atropine, and the findings had been extended to man.

The duodenal contents were drawn off by a tube, and the injection of secretin caused the formation of a large volume of enzyme-free fluid. If pancreozymin was injected when the fluid secretion had been established by secretin there was a slight increase in the rate of secretion, which then contained amylase, trypsin, and lipase. The preparations of pancreozymin were probably not completely pure, because contraction of the gall-bladder occurred, but they might make possible the development of more complete tests of pancreatic function in man.

Understanding of the regulation of gastric secretion had advanced similarly. Edkin's claim that a hormone, gastrin, which regulated gastric secretion could be extracted from the pyloric mucosa was opposed because of the discovery that histamine was a powerful stimulant of the oxyntic cells. But recently Komarov and others had extracted from the antral mucosa a protein-like, histamine-free substance which promoted the secretion of hydrochloric acid from the stomach. The search for a substance, analogous to pancreozymin, which would stimulate the secretion of pepsin had so far been unsuccessful.

Dr. R. E. DAVIES (Sheffield) dealt with the mechanism of secretion of gastric juice. "Pure" gastric juice was a mixture of the secretions from several types of cells. Recently, biochemical experiments on isolated gastric mucosa, using indicator dyes, had shown that the oxyntic cells were responsible for the secretion of hydrochloric acid at a concentration of 0.16 M, which corresponded to *p*H 1.4.

The acid was formed as such by the oxyntic cells and not in the form of a precursor. Using isolated gastric mucosal preparations, chiefly from amphibian stomach, it had been shown that the acid secretion depended on an ionic exchange. When the gastric mucosa secreted acid there was an uptake of carbon dioxide equivalent to the acid secreted. Hydrogen ions came ultimately from the water of the tissue fluid and blood and an equivalent amount of bicarbonate ions was passed into the blood in exchange for chloride ions; this explained the alkaline tide in urine after meals. The actively acid-secreting stomach required supplies of carbon dioxide from the arterial blood, and the rate of acid secretion could be so fast that the output of hydrogen ions might be much greater than the uptake of oxygen from the blood or the rate of production of carbon dioxide from metabolism in the stomach.

If in isolated gastric mucosa secretion was stimulated in the absence of external supplies of carbon dioxide, then ulcers and perforations might occur. Carbon dioxide prevented this, apparently by preventing the accumulation of alkali formed within the oxyntic cell concomitantly with the acid. Since many more hydrogen ions were formed than oxygen molecules used, most of the hydrogen ions must come initially from the water of the blood, and electrochemical work was needed to separate the positive and negative charges.

SECTION OF ORTHOPAEDICS

Tuesday, June 28

Fractures of Radius and Ulna

With the president, Mr. R. BROOMHEAD (Leeds), in the chair, Mr. E. MERVYN EVANS (Birmingham) opened a discussion on closed fractures of the shaft of the radius and ulna. He emphasized the virtues of non-operative treatment, basing his discussion on torsional derangements of the radius, which were insufficiently recognized. Failure to reduce them was the largest single element preventing an accurate position being obtained and kept. The best method of checking torsion was by comparative radiographs of the patient's opposite forearm in varying degrees of pronation and supination. Views of the upper end of the ulna and radius were taken of both limbs with a tube centred on the front of the forearm and tilted 20 degrees towards the elbow. On the fractured side the upper fragments were brought into equilibrium by the action of the

surrounding muscle, and it remained only to select the correct angle of lower forearm position by making a comparison with the shadow of the upper radial contours of the opposite forearm and then to correct length and angulation. Accurately reduced, the majority of these fractures remained stable, and retention in plaster was satisfactory. For oblique single fractures of the radius, or those also involving the distal end of the ulna, it was necessary to apply traction to the thumb for several weeks. In very few (even comminuted) fractures was it necessary to carry out open operation. Rules for the position in which to retain forearm fractures based upon their site did not hold. The higher the fracture was in the forearm, the more often did it appear that supination of the lower fragments was necessary, though the speaker's study of 50 cases showed that the torsion position was inconstant.

Mr. F. W. HOLDSWORTH (Sheffield) emphasized the need for open reduction and plating for those special types for which thumb traction had been advocated as well as for the majority of other fractures which, because of minor degrees of obliquity and comminution or of the great liability to soft-tissue interposition, were unstable or slow in uniting. Such a course enabled the case, within a day or two, to be treated as one almost of soft-tissue repair and without splintage. Such treatment was dependent upon perfect surgical technique, with avoidance of clumsy instruments and unnecessary soft-tissue damage.

Mr. I. LAWSON DICK (Bradford), in underlining Mr. Holdsworth's argument, mentioned the liability of the radius, after closed reduction, to angulate inwards, and that continued traction on the thumb or any other part of the hand brought its own problems of rehabilitation. Mr. H. H. LANGSTON (Winchester) pleaded for a critical assessment of the need for operation in every particular case, and Mr. N. ROSS SMITH (Bournemouth), while favouring closed methods, thought that some cases were better treated by the simple interlocking of fragments through small incisions. Mr. G. A. POLLOCK (Edinburgh) believed a middle course was right in most cases, for good function could be obtained in spite of interior defects of anatomical reduction.

Dr. F. W. HANFORD (Northern Rhodesia) felt that the advocates of open reduction had underestimated the risks of infection. Mr. H. H. HILL (Western Australia) felt that there were risks in the early movement of plated bones, and found function just as good in those cases in which closed reduction was maintained.

The discussion was concluded by Mr. MERVYN EVANS, who, while agreeing that open operation was rarely needed, thought that the decision should not be prejudged—a delay of two weeks was not harmful. Soft-tissue interposition, comminution, and minor obliquity did not in themselves provide reasons for open operation of any kind.

Lesions of Thoracic Inlet

A discussion on upper-limb pain due to lesions of the thoracic inlet was opened by Professor LAMBERT ROGERS (Cardiff), who described the anatomical relations of the bony circle that comprised the inlet, and the structures, normal and abnormal, which might cause compression, angulation, or chafing of the subclavian artery or the branches of the brachial plexus as they passed over the aperture. Man's assumption of the erect posture, and the dependent position of the limb, had favoured the angulation of these structures, whereas in the lower limb such lesions were unknown, because the evolutionary process had had a reverse effect. There were two types of case. The commoner, of neural origin, was due to the lowest trunk of the brachial plexus being stretched over and compressed against a cervical rib element of bony or fibrous nature, an abnormal first rib, the medial tendinous fibres of the scalenus medius muscle, or an abnormal scalene muscle. Professor Lambert Rogers felt that too much emphasis had been laid upon the scalenus anterior muscle—the medius was often more important. The less common (8 out of 35 operations in his series) type of case was vascular in origin and due to compression of the subclavian artery between the clavicle and a cervical or abnormal first rib. In cases of the neural type pain was of tingling character and mainly of ulnar distribution. In vascular cases the aching pain of ischaemia was associated with peripheral colour changes.

He condemned scalenus anterior tenotomy alone. Though necessary as a step in operative exposure, the exposure must be carried through to the actual site of compression, which should be dealt with adequately. The chief lesions from which these thoracic inlet disturbances must be distinguished were writer's cramp (hysterical) and cervical intervertebral disk protrusions. The latter were radicular in site and more cephalic in distribution, generally affecting the 5th, 6th, or 7th cervical segments. A useful test which also was of therapeutic value was splintage of the upper limb.

Mr. A. C. BINGOLD (Leeds) thought that the lesions under discussion should be termed the thoracic inlet syndrome, and he would add two others: Pancoast's syndrome, in which tumours in this space cause pain in the shoulder and inner side of the arm, intrinsic-muscle atrophy. Horner's syndrome, and, radiologically, an apical pulmonary shadow with more or less rib destruction. The other type was that shown by E. S. R. Hughes to be due to compression of the subclavian vein by a pre-venous phrenic nerve. A possible serious complication of compression of the subclavian artery between a cervical rib and the clavicle was aneurysm, from which, if thrombosis occurred, retrograde spread might cause embolism through the carotid artery and a contralateral hemiplegia. Many cases of thoracic inlet syndrome were in grossly overworked housewives; the usual treatment by rest, etc., was economically impossible. Much relief could be obtained by training such patients in scalene muscle relaxation and by galvanic treatment of the neck muscles—a cure usually being effected in six to eight weeks.

Mr. ROSS SMITH mentioned that there were other lesions of the cervical disk besides protrusion which caused symptoms, particularly in the elderly. These degenerative changes should be borne in mind in the differential diagnosis. Mr. HILL believed that the radiological evidence of protruded cervical disks was unreliable.

SECTION OF RHEUMATOLOGY

Tuesday, June 28

Rheumatoid Arthritis in the Young

Dr. BERNARD SCHLESINGER (London) said that a wider view of the clinical picture of rheumatoid arthritis with less emphasis on the locomotor system was more likely to cast fresh light on its aetiology. Study of the disease in its most acute form and from the onset in the young might be profitable. He had chosen for study 20 patients, all of whom suffered from considerable fever and the general acute manifestations first described by Still. The onset was usually abrupt, and began with arthralgia, followed by migratory arthritis, an urticarial or maculo-papular rash, adenitis, and sometimes splenomegaly. Fever was usually high and continuous at first, but later occurred in irregular periodic bursts. Complete recovery with no residual arthritis was the final result in four cases; 10 developed typical rheumatoid arthritis, two were still in the acute stage, and four patients died.

Apart from a slight degree of anaemia, the most significant change in the blood picture was a marked leucocytosis at the beginning of the disease, which soon dropped to normal. Leucopenia followed in a few cases, sometimes terminating in agranulocytosis. Leukaemia was the final result in two cases. Occasional complications were pericarditis, pneumonitis with pleurisy, and jaundice; rarely, cirrhosis and encephalitis were observed.

In many ways these 20 cases resembled some of the rarer arthritic disorders such as intermittent hydrarthrosis, angioneurarthrosis (Solis Cohen), palindromic rheumatism (Hench and Rosenberg), and Felty's syndrome. Comparison with lupus erythematosus and polyarteritis nodosa might help to elucidate the cause, and some allergic basis was suggested. The form of the antigen was probably bacterial, the initial leucocytosis being a sign of the primary invasion. The occasional leucopenia developing later with agranulocytosis and, rarer still, leukaemia might be due to repeated anaphylactic assaults on the bone marrow. The character of the fever, the clinical course, the regions involved, and the type of lesion in Still's disease all gave support to this theory, but many points remained obscure. N

one had yet discovered the nature of the antigen, explained how it produced a prolonged disease with progressive inflammatory lesions, or what predisposed certain individuals and allowed others to escape. In conclusion Dr. Schlesinger considered that "cortisone" might one day be used in the treatment of this disease, and in this connexion mentioned one of his patients who became hirsute when the illness itself had subsided.

Professor W. S. McR. CRAIG (Leeds) commented on the return to thinking in terms of endocrinology. The sex incidence in infective arthritis was of some interest in this connexion. In the adult it was most common in females at about 20 years and 45 years of age, the latter often coinciding with the climacteric. In the child infective arthritis came at the time of most active growth—namely, about the age of 5 years. He looked for some common factor such as infection, and pointed out that at the age of 5 years infection was usually acute, not chronic, and that foci of infection were more commonly found at that age.

He urged the need for research on a broad national basis, because of the comparative rarity of the disease and lack of clinical material. He considered that parallel studies should be carried out, and in this way it might be possible to check up on such factors as climate, soil, etc. He put in an earnest plea for treatment of the child in the home with home helps and visiting teachers rather than in residential special schools or convalescent hospitals. Professor Craig considered that more money should be spent on this type of case rather than as at present on patients with a less favourable prognosis. He thought that a generous diet was an important part of the treatment.

Dr. DONALD WILSON (Bognor Regis) commented on the rarity of the disease, but thought it was possible that this was exaggerated and that it was at times confused with other diseases. In treatment he emphasized that to avoid deformity orthopaedic measures were needed at an early stage. He gave an account of a child of 11 years he had seen suffering from this disease, treated with ACTH (adrenocorticotropic hormone) in a hospital in Philadelphia. There was alleviation of symptoms after three hours, and in eight hours all symptoms had disappeared. The child was running about and the E.S.R. was normal. The reversal of symptoms lasted eight days, and then the disease returned. Dr. Wilson thought that it was difficult to reconcile primary infection in the aetiology of Still's disease if cortisone or ACTH could cause the disappearance of all signs and symptoms in such a short space of time.

Dr. GEORGE D. KERSLEY (Bath) commented on shock as the trigger mechanism in precipitating the onset of Still's disease, and considered this another link in the theory of excessive strain on the adrenal cortex and anterior pituitary. He said also that the onset of the disease during the period of most rapid growth might point to changes in the anterior pituitary. He wondered if the effect of cortisone and ACTH on the blood picture, in that it caused a fall in lymphocytes and eosinophils, might have some bearing on the leucopenia and occasional agranulocytosis observed by Dr. Schlesinger in his series of cases.

In reply Dr. SCHLESINGER said that he did not regard diet as an important factor in Still's disease. Most of the children in his series came from well-to-do homes. He pointed out that, in a disease where orthopaedic and other measures were essential, admission to hospital was a necessity in the acute and subacute phases of the disease. He had not found gold therapy of any value, nor had he had good results with transfusions using blood from pregnant women, or with induced infective hepatitis.

Clinical Demonstration

Sir HENRY COHEN (Liverpool) demonstrated three cases from the Royal Bath Hospital of arthritis occurring in girls in the first decade of life: a child aged 5, whose illness had started at the age of 15 months: one aged 15, who gave a seven-years history; and a woman of 22 years, whose arthritis began at the age of 3 and had left her severely crippled.

Sir Henry stated that these three cases illustrated a lesson which still needed emphasis—that we were too apt to isolate as separate diseases under the labels of Still's disease, Felty's syndrome, and the like, a number of pathological states whose common feature was arthritis, implying that these might be the expression of differing primary essential causative factors. Experience showed that cases of so-called rheumatoid arthritis were part of a heterogeneous group of arthritides of unknown and probably of variable and dissimilar causation. Another point which it seemed timely to stress in view of the striking effects of cortisone in securing reversibility of the arthritic state was that the arthritic changes which in the early stages were reversible became in later stages irreversible. Cortisone would not replace destroyed articular cartilage or reduce subluxated joints. Early diagnosis and treatment would still be essential. Finally, Sir Henry emphasized the relation of peripheral vasospasm to the problem of arthritis and claimed that it was possible to recognize this as a major factor in the genesis of arthritis in some patients, a factor which possibly rendered the joints less resistant to the specific noxious agent.

Sir Henry demonstrated also a classical case of gout and a doubtful case of gout in a man of 29. Since the latter patient had an atypical history, a normal blood uric acid, and had not responded to anti-gout therapy, Sir Henry doubted the correctness of the diagnosis. The absence of tophi at his age was not of importance in excluding gout.

Dr. LESLIE C. HILL (Bath), in discussing these cases, agreed that the giving of individual titles to relatively rare diseases had no clinical value. He commented on the significance of peripheral vasomotor spasm as exhibited in the second case, and said that the incidence of this condition in patients with rheumatoid arthritis was higher than in the normal person. It might well be "the soil" in which this disease could develop. Discussing the third case, he indicated the danger of calling this a self-limiting disease, and emphasized the necessity for early orthopaedic measures.

Dr. SCHLESINGER said that the marked effusion into the joints in the second child was in his opinion a very good sign, as it made adhesions less likely; in his experience it was the only type of joint which defeated all orthopaedic measures.

SECTION OF TROPICAL MEDICINE

Tuesday, June 28

Tropical Diseases as Aftermath of War

Air Vice-Marshal T. C. St. C. MORTON said that the most important and the commonest tropical disease among ex-Service men was amoebiasis. The usual clinical syndrome was one of irregular bowel action with discomfort over the caecum, and the hepatic and splenic flexures relieved by the passage of flatus. The diagnosis was made by finding *E. histolytica* or cysts in the stool. The specimen should be sent, by post if necessary, to a centre which had special experience in this work. Sigmoidoscopy should also be performed. Amoebic granuloma of the rectum might simulate neoplasm, and discomfort in the right iliac fossa appendicitis. A correct diagnosis was important, because surgical intervention was contra-indicated. Liver abscess or hepatitis might also occur. After they had been treated it was important to sterilize the gut.

The treatment of amoebiasis of the intestine was by means of emetine bismuth iodide, reinforced by "diodoquin." If there was ulceration, and in chronic relapsing cases, penicillin and sulphasuxidine proved valuable in removing secondary bacterial infection and allowing the ulcers to heal: emetine was then more effective.

Colitis following bacillary dysentery was less common. It was treated by rest in bed, high protein diet, sulphasuxidine, and penicillin. Kala-azar might be found, especially in men returning from Bengal; it was often mistaken for undulant fever. Repeated marrow puncture might be necessary to establish the diagnosis. Treatment was by pentamidine.

Enteric fevers were particularly common among those stationed in the Canal Zone in Egypt. There was little risk of frank cases acting as carriers in this country, because of the careful examination before discharge from hospital, but mild atypical cases in inoculated persons might escape detection at the time.

Dr. A. R. D. ADAMS (Liverpool) agreed that amoebiasis was important and required thorough treatment. He relied mainly on emetine bismuth iodide given as enteric-coated pills. Diodoquin had proved disappointing. Chiniofon, given as a retention enema, had been valuable. Anyone who was found to be carrying cysts of *E. histolytica* should be treated, since symptomless infections might ultimately end in acute amoebic dysentery even after lying dormant for 23 years.

Amoebiasis was world-wide and flourished wherever sanitation was bad. He had found a family in this country, living under squalid conditions, several members of which suffered from acute dysentery. Stools from 100 women had been collected in a general hospital and *E. histolytica* had been found in five cases. These five women had not been abroad and none had suffered from dysentery. The true rate of infection was probably higher than was suggested by this particular investigation.

Dr. J. P. CAPLAN (London) described his experience in treating chronic intestinal amoebiasis at Queen Mary's Hospital at Rochampton. Emetine used to be the foundation of treatment, but sometimes it proved [illegible] might perhaps be due to a changed [illegible]; much of the present material was prepared by a synthetic methylation of cephaëline. Failure might also be due to concomitant infection with pyogenic bacteria; this should be treated by penicillin and sulphonamides. He now restricted the use of emetine to the treatment of complications of amoebiasis, such as liver abscess. His standard course was based on diiodohydroxyquinoline ("diodoquin") 0.8 g. three times daily for ten days. This was reinforced by quinoxyl enemata, although these rarely reached the caecum. Dr. Caplan also discussed the treatment of relapsing benign tertian malaria in ex-Service men. Radical cure was best achieved by a combined course of quinine and pentaquine given for ten days in hospital.

Sir GORDON COVELL (London) discussed the diagnosis and treatment of malignant tertian malaria. For prophylaxis he recommended proguanil (paludrine) or alternatively chloroquin. Quinine might cause blackwater fever in exceptional cases, and mepacrine psychosis; it also stained the face yellow. Chloroquin also might on rare occasions have toxic effects. He therefore used proguanil, but reinforced it with 900 mg. of mepacrine on the first day to reduce the fever more rapidly and to diminish the possibility of subsequent relapse.

Loaiasis

Professor G. J. STEFANOPOULO (Pasteur Institute, Paris) spoke of loaiasis, which was common among Europeans working in French Equatorial Africa. Besides the well-known Calabar swellings there were other symptoms due to sensitization which might resemble acute rheumatism, synovitis, lymphangitis, Hodgkin's disease, or tropical eosinophilia. Later the patients became desensitized and most of the symptoms subsided, but pruritus and eruptions might occur. Geographical factors had to be borne in mind in making the diagnosis. Leucocytosis and eosinophilia would be found, and there were microfilariae in the blood in 40% of cases. Intradermal and complement-fixation tests were valuable, *Litomosoides* from cotton-rats being used as antigen.

Previously, specific treatment was unsuccessful, but "hetrazan," which was given by mouth, had a marked effect. Microfilariae disappeared from the blood in 48 hours. At first all the allergic symptoms reappeared or were increased—especially oedema, pruritus, and rashes, which might be papulovesicular or urticarial. After two days, however, these symptoms subsided. Relapse was common. He gave 400 mg. a day for 10 days and repeated this course several times at monthly intervals. He was investigating the possibility of using hetrazan prophylactically to protect French engineers who visited West Africa for limited periods.

Dr. F. HAWKING (National Institute for Medical Research, London) spoke of the valuable work carried out by Dr. D. M. Blair and Mr. Alves on schistosomiasis in Southern Rhodesia. He mentioned the new compound "miracil," or "nilodin," which could be given by mouth and cured infections with *S. haematobium*. He also described the work of Col. W. Laurie and himself on hetrazan in the treatment of filariasis due to *W. bancrofti*. The action of hetrazan on adult worms was doubtful, but it was very effective in destroying microfilariae; apparently it acted as an opsonin. It would probably be useful for the mass treatment of whole villages infected with *W. bancrofti*, so as to prevent further transmission of the disease.

Professor H. E. SHORTT showed lantern slides depicting his now historic discovery of the exo-erythrocytic cycle of the malaria parasite in the liver, a discovery which he and his colleagues described in the *Journal* of Jan. 31, 1948 (p. 192), March 20, 1948 (p. 547), and June 26, 1948 (p. 1225). Dr. H. STEINITZ (Tel-Aviv, Palestine) discussed a new syndrome, "eosinophilic erythroedema," which had appeared in Palestine during the last seven years. Its cause was still unknown, but all the patients gave a positive response to filarial antigen.

Dr. G. W. M. FINDLAY (London), president of the Section, spoke briefly on aureomycin.

SECTIONS OF MEDICINE AND SURGERY

Wednesday, June 29

Treatment of Peptic Ulcer

With Professor R. E. TUNBRIDGE (Leeds), president of the Section of Medicine, in the chair, Sir HENRY COHEN (Liverpool), opening the discussion, characterized peptic ulceration as the most important social and economic medical problem after the group of rheumatic diseases. In this country 1½ million persons were computed to suffer or to have suffered from peptic ulcer, and one-half of the males between the ages of 45 and 54 in the County of London. Peptic ulcers had in common a restriction of site to areas with which acid juice came in contact. If the proteolytic ferments and acids were subjected to an increase in their strength or in the duration of their action, an ulcer might be expected to follow, and a reduction in the resistir power of the mucosa exposed to them would have a simil effect. Local vascular or inflammatory disturbance, f example, might lead to a lowered resistance of a mucos area and render it susceptible to the ferments. Spiced foo might effect a local irritation of the oxyntic cells, but in gener such a local cause was unimportant; they must usually see a more distant and usually nervous cause. Anxiety or hypo thalamic disturbance might produce an excessive secretion of juice unusually rich in acid. In addition to the direct neural mechanism there was a humoral mechanism, perhaps also subject to vagal influences, and dependent on the secretion by antral cells of a hormone called gastrin, which stimulated acid production. The gastrin-secreting cells might be stimulated excessively by local irritative or inflammatory processes, by disturbances in neural control, and perhaps by regurgitating bile.

Treatment must aim at diminishing acid pepsin secretion and increasing mucosal resistance. (1) The neural secretion might be attacked (*a*) at a mental level by adjustment of the individual to his environment and by the administration of sedatives, particularly of the barbiturate group, or (*b*) at a peripheral level by atropine or vagotomy. (2) Hormonal secretion had been attacked, not very successfully, by Ivy's enterogastrone, an extract of intestinal mucosa, and by the administration of extract of pregnant mare's urine. Partial gastrectomy aimed at the same effect. (3) Attempts might be made to buffer acids by the frequent administration of food, to neutralize them by alkalis, to effect their absorption by certain synthetic resins, to dilute them by water, or, surgically, to dilute and neutralize them by allowing intestinal juice to enter the stomach. (4) Gastrectomy, increasingly radical, had been employed, apparently on the general principle that without an ulcer-bearing area there could not be an ulcer.

Of the complications of peptic ulcer, perforation and stenosis required surgical treatment, and haemorrhage was increasingly treated by the surgeon too. Ulcers must be regarded as mere incidents in the life of the subject of the ulcer diathesis, and treatment must be directed to the patient as a whole rather than to his gastric mucosa alone.

Dr. C. N. PULVERTAFT (York) read the paper by the late Mr. A. HEDLEY VISICK—almost completed before his death. The two Sections had stood silent in tribute to his memory for a minute when the meeting opened. In selecting a scheme of treatment for an actual patient, the knowledge of the general practitioner, who alone was familiar with that patient as a whole man, was of paramount importance. Treatment would vary too from district to district, the family doctor being guided in his choice by the facilities for particular types of treatment in his own area. Patients with a long history of the disorder, previous perforation, gastro-jejunostomy already performed, and persistent pain usually required surgery. The patient's emotional constitution must be considered, and his economic situation. The local pathological nature of the ulcer, the scarring or stenosis it may have produced, and its deep penetration were of importance too.

The first method—ambulatory treatment at home—must be carried out by the family doctor, with repeated follow-up by institutional methods. Men under the age of 30 could be treated with high efficiency and complete safety by gastrectomy. The indications for medical treatment were (1) economic unsuitability for surgery, (2) economic suitability for prolonged inactivity under medical care, (3) absence of stenosis, (4) short history, and (5) a pronounced anxiety state. Repeated haemorrhage or perforation and the suspicion of malignancy were absolute indications whatever were the attendant circumstances.

Of surgical methods, gastro-jejunostomy was a safe operation for patients over 50 with stenosing duodenal lesions. Vagotomy had not yet been finally assessed. Gastrectomy aimed at producing complete and permanent achlorhydria. To achieve this effect the gastrectomy should leave a remnant of stomach measuring 5 in. by 2 in. (12.7 by 5.1 cm.), though when performed for jejunal ulceration the remnant should measure only 1 by 1.5 in. (2.5 by 3.8 cm.), and the whole greater curvature should be mobilized, with division of all vasa brevia. The operation must be regarded as only an incident in treatment, and dietetic and sociological matters must be adjusted after it, though a full diet, alcohol, and smoking were usually permissible a week after operation.

Mr. A. DAVIS BEATTIE (Leicester) considered gastrectomy to be the only successful treatment for large or complicated peptic ulcer, but it seemed an unaesthetic and unnecessarily drastic procedure to carry out in cases of duodenal ulceration, and its results showed a smaller proportion of full economic successes than was generally realized. Vagotomy seemed a more physiological operation. Its rationale was based on the reduction of gastric acidity, particularly of the night secretion, and the relief of muscle spasm which followed it. Experience of 200 cases of vagotomy suggested that the operation was particularly suited to (1) uncomplicated duodenal and pyloric ulcers, (2) recurrent or jejunal ulcers after gastrectomy, and (3) small early ulcers of the lesser curvature, especially towards its upper end. The transabdominal approach was preferred to the transthoracic, since it permitted determination of the extent and nature of the ulcerative process.

Vagotomy was followed by an immediate loss of pain. A temporary ileus of stomach and small bowel lasted 24 to 48 hours, to be followed by a gradual increase in intestinal motility during the succeeding 12 to 18 months, and consequent relief of any previous tendency to constipation. Temporary post-vagotomy cardiospasm always resolved spontaneously after 2–3 weeks. Pylorospasm was the only cause of persistent post-operative symptoms and was responsible for nearly all failures. Retention symptoms were present in some degree in 65% of cases, were objectionable in about half of these, and were incapacitating in about 15%.

Apparent recurrence of ulcer symptoms seemed always to be due either to incomplete neurectomy or to retention; in no case could it be proved to be due to persistent or recurrent ulcer. The frequency of retention symptoms had led him in the last 100 operations to combine vagotomy with pyloroplasty or gastro-jejunostomy, and a certain proportion of the first 100 patients treated had subsequently required one or other of these additional procedures. Vagotomy, supplemented by pyloroplasty (preferably) or gastro-jejunostomy, afforded complete relief from all dyspeptic symptoms, improvement in psychological outlook, and the ability to return to full work six weeks after operation.

Dr. RICHARD DOLL (London) discussed the sociological aspects of peptic ulceration. In the latter half of the last century 50% of perforations were in women under 25 years of age, but since 1920 90% had been in men. A similar change had overtaken the incidence of haematemesis. It thus seemed reasonable to deduce that sociological influences were at work. Geographical differences in the incidence of peptic ulceration supported this deduction. Differences in the social scale, too, affected ulcer incidence; deaths from gastric, but not duodenal, ulcer were more numerous relatively among the poor than among the wealthy. An investigation by personal interview of 5,950 ulcer patients, 80% of whom had had a positive radiological, gastroscopic, or operative diagnosis, had been conducted by the speaker and Dr. Avery Jones. The standardized morbidity ratios showed that the incidence of ulcer was highest in doctors. The incidence was average in bus and trolley drivers, lower than average in agricultural workers. Sedentary workers had a low incidence too, not statistically very convincing, but perhaps rendered less dramatic because some ulcer patients had been transferred to clerical work as part of the treatment of dyspepsia. There was no difference in ulcer incidence between men on regular hours and men on shifts, between those who had regular and those who had irregular meals, but perhaps a low incidence in the latter group was obscured by ulcer patients having moved, under advice, from the latter group to the former.

There had been a rise in the incidence of ulcer during the recent war due to industrial fatigue rather than to danger, for the incidence of perforation in Glasgow reached its peak before the air attack on that city (Illingworth). Anxiety at work was of high importance, but only in cases of duodenal ulcer, not gastric. Food processing and smoking were under investigation now, and preliminary results seemed to show no difference between the incidence of ulcer in smokers and in non-smokers. The changed sociological relations between children and parents now as compared with the last century might be of importance in the increase in ulcer-incidence, and Halliday had blamed very tentatively an unhappy background during the first five years of life for the subsequent development of ulcer. One interesting effect of the survey was that it revealed gastrectomized patients happily and successfully performing all kinds of work, even the heaviest manual labour.

Dr. CORNET (Paris) said that ulcers of the anterior wall of the stomach were difficult to detect and follow by radiological methods, and their presence could sometimes be proved only by gastroscopy. Even gastroscopy had its own difficulties, the great oedema around these ulcers sometimes simulating malignant disease.

Dr. J.-J. SPIRA (London) said that hydrochloric acid played no part in acute ulceration, but no chronic ulcer formed in the absence of acid. Chronic ulcers might be classified according to their situation on a mucosa which normally secreted alkali (oesophagus, jejunum, Meckel's diverticulum) or acid (stomach, first part of duodenum). Acid, pepsin, or an acid–pepsin mixture alone could not produce ulcer. A second factor was also required, and that was the presence of bile in the stomach.

Dr. J. LIPETZ (Edinburgh) recommended the greater use of the Gregersen slide test for the detection of occult blood in the stool as a convenient and reliable method for the general practitioner to select those of his dyspeptic patients who suffered from gastro-duodenal ulceration. Dr. D. R. BELLETTY (Assam) had found a high incidence of peptic ulceration in his coolie patients, who were meat-eaters when they could get meat, fairly heavy drinkers when they could get drink, and heavy smokers when they could get tobacco. Dr. MONTGOMERY (Montreal) reported that in North America they were coming to the opinion that the late results of vagotomy did not entirely fulfil the early promise of that operation. Dr. C. M. STEVENSON (Cambridge) blamed the cigarette but not the pipe for ulcer-production. Dr. D. A. JENNINGS (London) had found that only three of over 300 patients on ambulatory out-patient treatment had continued to have pain. The real difficulty was to get the patient off milk and back to work. The principles of treatment were primarily psycho-analytic—the patients must

be taught to relax and to abandon, not merely to reduce, their smoking. Controlled American experiments with nicotine-free cigarettes clearly showed the importance of nicotine in ulcer-production.

SECTIONS OF OBSTETRICS AND GYNAECOLOGY AND RADIOLOGY

Wednesday, June 29

Radiography and Disproportion

Mr. ARNOLD WALKER (London), vice-president of the Section of Obstetrics and Gynaecology, called upon Professor Chassar Moir (Oxford) to open the discussion. Professor CHASSAR MOIR said he believed that distrust of pelvimetry had arisen because radiologists as a class had little first-hand knowledge of obstetrics and often failed to appreciate the intricacies of childbirth. Similarly, the obstetrician seldom appreciated the technical difficulties of *x*-ray methods. He pleaded for close co-operation between obstetrician and radiologist if progress was to be made. Disproportion was the most important of the causes of dystocia, and it was right that it should have special consideration, though measurements of it took no account of such important features as the force and frequency of the uterine contractions, the adaptation of soft tissues, or the moulding of the baby's head. Least of all did radiology measure the patient's psychology.

Adequate pelvic examination necessitated much more than recording the size of the conjugata vera, important as that time-honoured measurement was. Radiological measurement had to include examination of the pelvis in more than one projection, and shape as well as pelvic size was important. The occipito-posterior position of the head, for example, was often associated with a pelvis greater in its antero-posterior than in its transverse measurements. Disproportion could be assessed by various methods. There was the "impressionistic" method, seen at its best in the stereographic technique used by Caldwell and Moloy. This was, however, a time-consuming method. Ball and Marchbanks, of New York, had developed a method of computing head volume and comparing it with pelvic capacity, but this suffered because the technical difficulties were formidable. Nicholson, of Moreton-in-Marsh, had related the pelvic area at brim level and at ischial-spine level to the progress of labour, but he had paid little attention to the size of the foetal head and he had not considered sufficiently the variation of prognosis that derived from variation in pelvic shape. However, Nicholson was to be congratulated on focusing attention on the need for accurate measurement; that work had been done in a busy general practice in a rural district. Roland Williams and the speaker had developed methods by which pelvic outline could be reduced to true size and shape and the charts used for estimating the "fit" of the foetal head. A strict analysis of 193 assessable cases of clinically suspected pelvic abnormality had been carried out, with the following results: When easy labour was indicated by the graphs, the labour in 72% of cases was short, spontaneous, and uneventful; when difficult delivery was indicated, labour was prolonged or required operative assistance in 86% of cases. The accuracy was even higher when dystocia was indicated by contraction in the brim graph, as distinct from the cavity and outlet graphs.

Dr. J. BLAIR HARTLEY (Manchester) said that often the radiologist was reporting to more than one group of obstetricians, and he pleaded for simplification and standardization of methods so far as practicable. No routine examination should comprise more than four films: (1) An A.P. view of the whole field; (2) a lateral view showing the whole of the pelvic canal and as much of the uterus and foetus as possible; (3) an outlet view; and (4) a P.A. view to study and "measure" the foetus—that is, the assessment of available diameters of the foetal skull and of development and normality of the foetal skeleton and skull. He was usually able to assess maturity to within a few days. He disagreed with taking a supero-inferior view through the pelvic inlet, because in this position the foetal breech was most likely to lie in the central beam of the *x* rays and nearest to the tube, a fact which might cause damage to gonadal tissues. So far there was no reliable information on that point. In general, mid-pelvic diameters were the ones requiring most careful study, especially in relation to pelvic mobility. Co-operation with the obstetrician was essential.

Miss MEAVE KENNY (London) said that she was an "impressionist," believing in the value of stereoscopic *x*-ray pelvimetry. There was a great need for the accurate measurement of the pelvis, for although the infantile mortality rate had fallen considerably in the last half-century there had been no difference in the figures of the years 1900 and 1947 of deaths in the first day and first week due to birth trauma (Martin, *British Medical Journal*, 1949, 1, 438). The day might come when every woman would have her pelvis *x*-rayed. There was no absolute indication nowadays for caesarean section, and the incidence of this operation had not risen because of *x*-ray pelvimetry.

Dr. S. JOSEPHS (Newcastle-upon-Tyne) described his method of cephalometry. He said that 30 cases had now been collected in which radiological cephalometry had been performed twice, and in no case had there been any evidence of growth during the last four weeks of pregnancy. That investigation was continuing, with estimations of foetal skull size at 32 weeks, 36 weeks, and at term.

Mr. LINTON M. SNAITH (Newcastle-upon-Tyne) said that he had been associated with Dr. Josephs in this important discovery. He stressed the importance of estimating mid-cavity pelvic size, and labour should not be allowed to proceed where it was inadequate. Dr. ALAN BARKER (East Kent) thought Professor Moir's charts were the answer to the general practitioner's problems.

Dr. A. J. MACLEOD (North Uist) thought ossification of the foetal skull was more important than size. Mr. J. A. STALLWORTHY (Oxford) described himself as an "unbeliever" and maintained that after two years' experience a registrar could give a better forecast of the outcome of a labour by clinical means than by using the available radiological methods. Professor T. N. A. JEFFCOATE (Liverpool) advocated the uses of trial labour and of "intranatal" radiology (*x*-ray examination during labour).

Others taking part in the discussion included Mr. C. SCOTT RUSSELL (Manchester), Mr. ARNOLD L. WALKER (London), Mr. R. NEWTON (Manchester), Dr. R. D. B. WRIGHT (Hull), Dr. T. F. REDMAN (Manchester), Dr. J. LÖVSET (Norway), and Mr. G. GORDON LENNON (Oxford).

SECTIONS OF PATHOLOGY AND BACTERIOLOGY AND TROPICAL MEDICINE

Wednesday, June 29

The Sprue Syndrome

Dr. J. G. GREENFIELD was in the chair for the first part of the meeting and Dr. BALFOUR KIRK for the second.

Professor A. C. FRAZER (Birmingham) defined the sprue syndrome as including tropical and non-tropical sprue and the coeliac syndrome. Fat absorption was constantly affected, and on this background of steatorrhoea such things as watery diarrhoea, vitamin deficiencies, and haematological changes were superimposed in varying degree. The fat-absorption defect was a partial one, and could be related to the amount of fat fed. The sprue patient was intolerant of saturated fatty acids, and the fat in sprue stools was mainly of this type, though short-chain volatile fatty acids might also be greatly increased. The usual increase in particulate blood-fat (chylomicrons) after a fatty meal was absent in the sprue syndrome. When particulate fat absorption was impaired more fat might be hydrolysed, and there might be increased mucus formation in the intestinal lumen, leading to further interference with particulate fat absorption, and also possibly to flocculation of barium sulphate emulsion, giving rise to the characteristic deficiency pattern seen radiologically. The vitamin deficiencies which were so characteristic of the established sprue syndrome might be associated with an increase of the bacterial population of the intestine. These might invade the small intestine, and even the stomach in achlorhydric patients, and their competition for the vitamins in the diet would impoverish their host. Alterations in dietary fat and an increased susceptibility to overgrowth of intestinal bacteria might account for the increased incidence of the sprue syndrome under tropical conditions.

Professor Frazer's address was followed by a brisk discussion. Professor R. J. V. PULVERTAFT described work in which he had removed the ileo-caecal valve in dogs, thereby allowing colonic bacteria to invade the small bowel; no blood changes had followed this procedure, and steatorrhoea had not been observed. In reply, Professor FRAZER suggested that possibly the quantitative conditions needed for producing steatorrhoea had not been attained. Dr. G. M. FINDLAY asked if there were any explanation for the absence of sprue in tropical Africa; Professor FRAZER quoted work done by Dr. J. M. French in his department, which demonstrated that the type of dietary fat might influence the appearance of the sprue syndrome. There were considerable differences in the fats eaten in India and in Africa. Dr. J. P. CAPLAN asked why prisoners in Japanese hands had failed to developd the sprue syndrome, although on a very deficient diet. This was explained by the very low fat content of their diet, too low to enable steatorrhoea to become apparent.

Dr. D. A. K. BLACK (Manchester) suggested that although impairment of fat absorption was perhaps the most obvious and characteristic feature of the sprue syndrome, it was probably always attended by defective absorption of other substances, though this might not be apparent clinically. He had recently seen a patient who presented a case of iron-deficiency anaemia. Steatorrhoea had been found, and intravenous iron had given a good haematological response, although the anaemia was refractory to iron given by mouth. To the pathologists Dr. Black commended the virtues of a three-day fat-balance test in the diagnosis of doubtful cases of steatorrhoea. When steatorrhoea was obvious on inspection of the stools laboratory tests were not needed. It was important to bear in mind the danger of salt depletion in those patients with sprue in whom there was severe and long-continued diarrhoea. Liver and sulphaguanidine had proved effective in arresting watery diarrhoea in the sprue syndrome.

Dr. K. D. KEELE (London) had had an unusual opportunity of observing the early stages of tropical sprue during his work in Bihar and later in Poona. His experience had led him to distinguish a stage of "onset or relapse" and a stage of "remission." In the early stages diarrhoea was present in 80 to 90% of cases. Anorexia and vomiting were also common. With the appearance of remission, which might happen spontaneously or be induced by liver therapy, these symptoms became less marked, but often abdominal distension or a sore tongue appeared. There was considerable dissociation between the degree of steatorrhoea and the clinical state of the patient. For instance, liver could induce a complete clinical remission without the steatorrhoea disappearing. The action of liver seemed to be to enhance the absorption of water-soluble substances, but not of fat. In the aetiology of sprue, a high fat content of the diet probably played some part. In view of the high incidence of sprue in India in the hot season it would seem that a high effective temperature might precipitate sprue.

Dr. A. W. D. LEISHMAN (Sheffield) spoke of the blood changes in sprue. Marrow biopsy had increased knowledge of the anaemias of sprue. In early sprue severe anaemia was uncommon. In established sprue the anaemia might be macrocytic in type, although a megaloblastic bone-marrow was rather uncommon. This type of anaemia might well be analogous to the anaemia produced in rats by intestinal manipulation. In another type of anaemia found in sprue the haematological stigmata of iron-deficiency complicated the macrocytic anaemia. When the bone-marrow was megaloblastic there was a good response to folic acid; otherwise the response was poor. Macrocytic anaemia must be looked on as a delayed complication rather than as an essential part of the sprue syndrome.

In the concluding discussion Air Vice-Marshal T. C. MORTON contended that the widespread use of sulphaguanidine in suspected cases of dysentery might explain the high incidence of sprue in the 1939–45 war. He also quoted Sir Patrick Manson's dictum that "sprue is the past participle of spree." Dr. G. M. FINDLAY asked whether the type of fat present in the "K diet" might be responsible for the high incidence of sprue in men who had taken this diet. Dr. KEELE, while disclaiming knowledge of this type of fat in the diet, was emphatic about its nauseating properties.

SECTION OF RADIOLOGY

Radiotherapy in Spondylitis Ankylopoietica and Osteoarthritis

With Professor B. W. WINDEYER, vice-president, in the chair, the subject of radiotherapy in spondylitis ankylopoietica and osteoarthritis was opened by Dr. E. L. GWENDOLEN HILTON (London). The first of these conditions, she said, was often a crippling disease and attacked mostly young men. Gold therapy, which was very useful in rheumatoid arthritis, was of no value in the treatment of spondylitis. She had also seen patients who had been treated for months with vaccines but had steadily got worse. With *x*-ray therapy beneficial results began almost at once. Her remarks were based on nearly 1,500 cases, all of which had been carefully followed up. It was extremely easy to miss the early radiological appearances in spondylitic joints. Not all cases progressed to complete bony ankylosis of the whole spine. The disease might become quiescent spontaneously at any stage. In some cases the disease affected the spine only and not the peripheral joints at all; in others it might affect many of the peripheral joints early in its course. When once bony changes occurred they were permanent. In spite of complete clinical cure she had never noticed any radiological evidence of reversal of bony change.

Patients often asked whether *x*-ray treatment would have any deleterious effect, particularly on the genital organs. If the scrotum was properly protected no damage was done to male genitalia during treatment. In the female it was more difficult, because the ovaries came within the direct beam of the rays when the sacro-iliac joints were exposed, though if the joints were irradiated obliquely the dose received was reduced and amenorrhoea was not produced in every case. In young women *x*-ray treatment of the sacro-iliac joints should not be given unless it was essential; it should be given only if the woman was ill and incapacitated by disease. Finally, she had noticed a considerable difference in the progress made by patients who had received identical *x*-ray treatment but who, on the one hand, had had physiotherapy in her own hospital, and, on the other, had had physiotherapy elsewhere, administered by people who had less experience in dealing with spondylitics. The treatment should be adapted to the individual in each case.

Dr. MARGARET D. SNELLING (London) presented details of a series of cases of spondylitis treated at Middlesex Hospital. The aim of *x*-ray treatment had been to get rid of acute symptoms, restore function, and prevent recurrence of attack. About 300 cases of ankylosing spondylitis had been treated during the period 1937–47. Nearly all of them were males, and the great majority were in the second stage of the disease, in which the disease was active and affected the whole or most of the spine, Of the cases in this stage and in the first stage, with the disease active but localized, much improvement in symptoms within three months of treatment was recorded in 69%. Of 66 patients in the second stage whose progress was followed from three to five years after initial treatment, 48 showed marked improvement in symptoms and 35 marked improvement in signs. It was of the greatest importance to undertake physiotherapy and all adjuvant treatments.

Dr. L. JANET MALLENDER (Leeds) said that in the treatment of osteoarthritis radiotherapy was new; it did not replace the older and long-tried methods but it might offer an alternative. Opinions about the value of radiotherapy differed; it had been suggested that the effect was purely psychological. She presented figures relating to 259 patients with osteoarthritis. She formed the impression that small joints did better than large ones. The dissected figures were as follows:

	Relieved for More than 6 Months	Relieved for Less than 6 Months	Unrelieved
Males 117	55·5%	23%	21·5%
Females 142	46·5%	25·5%	28%

After quoting other figures, she said that *x*-ray therapy in osteoarthritis offered a most useful degree of palliation, and was well worth the small amount of trouble it entailed.

Professor B. W. WINDEYER said that in osteoarthritis radiotherapy should not be used when other simpler measures were likely to be effective. Dr. J. S. FULTON (Liverpool) considered that the value of radiotherapy in osteoarthritis was not as clearly known as it might be. As for *x*-ray therapy directed to the sacro-iliac joint, he did not think it could be given without involving the ovaries, and in his view it should not be given to women capable of bearing children.

SECTION OF ANAESTHETICS

Wednesday, June 29

Post-operative Pulmonary Complications

With the President, Professor R. R. MACINTOSH (Oxford), in the chair, Dr. E. M. BUZZARD (Oxford) began by considering lung abscess. This condition was very difficult to diagnose without *x*-ray examination. The once-common classical picture of the "putrid lung abscess" was now rare because of pre- and post-operative penicillin. The onset was insidious and often symptomless, and bronchoscopy had little place in its treatment. In its early stage the lesion was beyond reach of bronchoscopy. Surgical help should be sought early. There were two types of post-operative pneumothorax. In one, the condition was induced by misplaced paravertebral block needles, and in the other it occurred after an acute obstruction in the respiratory tract. Air escaped from the alveoli into the interstitial tissue and so into the pleura. The early recognition of atelectasis was important if the patient was to be spared prolonged convalescence and the possibility of bronchiectasis.

In the detection of atelectasis at the bedside reliance should be placed on physical signs rather than *x* rays. The characteristic onset within 36 hours of operation and the mediastinal shift shown by tracheal deviation were unmistakable features. Percussion and auscultation confirmed the diagnosis.

In treating atelectasis after abdominal operation bronchoscopy was not a beneficial procedure as a routine. He restricted its use to those weak people who could not cough up secretion themselves. After thoracic operations, however, particularly where purulent secretion was present, bronchoscopy might be life-saving. Carbon dioxide inhalation was of little value; complacency of the attendants was induced and voluntary effort of the patient interfered with. The possibility of the plug being sucked further into the bronchial tree could not be discounted. The incidence of atelectasis was higher after abdominal operations than after operations on other parts of the body, because of the presence of pain and muscle-splinting and possibly a viscero-bronchial reflex.

Dr. H. J. V. MORTON (Uxbridge), discussing the methods by which knowledge of the condition had been derived, emphasized that all complications should be recorded, particularly the minor ones. As a result of this practice the published morbidity rates had grown higher. The only technique for investigating post-operative atelectasis was by personal and repeated observation of cases. Experiments should be deliberately planned for the study of some particular aspect of the problem, and strictly comparable groups of cases used for control. Standard tests of significance should be applied to the data so obtained. Less rigorous methods would perpetuate confusion.

Mr. DONALD S. M. BARLOW (London), speaking as a thoracic surgeon, recognized three groups. In the first the chest was healthy but a bronchus had a mechanical block. In the second infection was present, with a true pneumonia or bronchitis. In the third there was both a mechanical block and infection. In the last group pre-operative lung disease was often present; it might be unsuspected pulmonary tuberculosis. The following factors might lead to atelectasis: aspiration of foreign material into the respiratory tract; operation in the presence of respiratory infection; too much atropine interfering with the normal moisture in the respiratory tract; and long-standing oesophageal obstruction. The oesophagus and stomach should be empty before operation, since fluid might run into the trachea without being noticed. He did not believe that a reflex was connected with atelectasis. The condition was rare in thoracic cases because it was not allowed to occur in hospitals where chest operations were performed. During operation the anaesthetist should be ready to employ suction if necessary. Patients should be oxygenated during the operation and for at least twelve hours after. Coughing was the main item in treating atelectasis. Bronchial plugs should not be allowed to remain for more than 48 hours or there was risk of ulceration of the mucosa. The prevention of chest complications should be part of the duty of the anaesthetist.

Dr. DONALD TEARE (London) described post-operative pulmonary complications in patients who had died within 24 hours of operation. Some died during recovery from asphyxia and anoxia. He had seen pneumothorax as well as air embolism from penetration of the lung by needles during regional block. With regard to atelectasis, the two prime factors were respiratory obstruction and a weak inspiratory effort. Curare could produce both of these by means of bronchospasm and respiratory depression.

Dr. JOAN MILLAR (Newcastle-upon-Tyne) discussed prophylaxis against atelectasis. Pre-operatively, attention was directed towards existing respiratory infection. A radiograph was taken, breathing exercises were initiated, and oral sepsis was treated. During operation she used adequate oxygen, light anaesthesia, and either intubation with suction or gravity to control secretions. Most anaesthetic techniques were equally good; ether did not increase the liability to atelectasis. Post-operatively, endobronchial instillation of penicillin was an important treatment.

Dr. B. G. B. LUCAS (London) showed that during inspiration the bronchi were larger than during expiration. He had tried to produce bronchial dilatation by administering ephedrine for two days pre-operatively. Nebulized amethocaine caused dilatation for a short time, and once the bronchi had closed down again ephedrine was useless. The possibility of oedema of the mucosa and damage to the cilia made that use of local analgesia unsuitable.

Professor R. R. MACINTOSH described cases of pneumothorax which had followed paravertebral block. He had used intravenous procaine as an analgesic after operation and wondered whether its beneficial effect might have been partly due to relaxing bronchospasm. Dr. W. W. MUSHIN (Cardiff) drew attention to the work of Hilding, who had demonstrated that negative pressure and airlessness of bronchi could be produced by the centrifugal movement of mucus films in the bronchial tree. Dr. T. CECIL GRAY (Liverpool) doubted whether bronchospasm ever occurred in human beings as a result of curare. Dr. A. R. HUNTER (Manchester) believed that pulmonary complications were primarily infective in origin. Dr. J. A. G. HORTON (Newcastle-upon-Tyne) had examined the sputum of patients before and after operation. A number of the post-operative samples contained pathogenic cocci not present before operation. Dr. R. F. WOOLMER (Bristol) inquired whether expectorant drugs had any place in the treatment of atelectasis. Dr. BUZZARD doubted whether there were any real expectorants. Drs. H. R. YOUNGMAN (Cambridge), KATHLEEN E. THOMPSON (Morecambe), H. B. WILSON (Aberdeen), G. S. W. ORGANE (London), A. H. GALLEY (London), and W. S. MCCONNELL (London) also took part in the discussion.

SECTION OF ANATOMY AND PHYSIOLOGY

Wednesday, June 29

Anatomy and Physiology of the Skin

Professor H. BARCROFT (London), who spoke on "Factors Regulating Blood Flow in the Skin," reviewed methods of examining and measuring circulation in the skin. For the most part these methods could only be applied to the distal parts of the limbs, parts containing a large proportion of skin with a specialized circulation. Among them were observations on the temperature of the skin of the digits; plethysmographic recording of blood volume or blood flow changes in the digits or in the hands or feet; calorimetric measurement of the heat given out by the blood stream in the fingers; the display of subcutaneous veins by infra-red photography; and the determination of the circulation time by fluorescein.

He then gave an account of recent work. Arnott and Macfie had shown that the blood flow in the fingers was increased by

heating only part of the body; this vasodilatation was caused by inhibition of vasoconstrictor tone rather than by the action of any vasodilators. Light falling on one part of the body caused vasodilatation in another part (Cooper and Kerslake). This was not due to local heating of the blood and a consequent rise in body temperature, because it occurred after occlusion of the arterial supply to the part exposed to light. Vasoconstriction in the skin of the fingers caused by deep breathing continued even after spinal section in man, unlike the vasoconstriction due to psychic reactions. It would appear that there were spinal vasomotor reflexes. Increased blood flow in the skin during pregnancy was suggested by the dilated veins which could be demonstrated by infra-red photography (Bowes). Fluorescein injections had been used to assess the vascularization of the pedicles of skin grafts. The effects of sympathectomy on cutaneous blood flow have been followed in the post-operative period; the immediate dilatation was followed by a rapid return of tone to the cutaneous vessels. It was pointed out that plethysmography offered a means of assessing the action and value of vasodilator drugs.

The discussion which followed this paper centred largely on the changes in cutaneous blood flow which occurred during pregnancy, and it was agreed that there is clinical evidence of vasodilatation.

Dr. C. A. KEELE (London) said that sweating was controlled by (1) stimuli causing sweating, (2) the efferent nerve pathways concerned, (3) the chemical transmitter between nerve endings and sweat glands. Kuno differentiated between "mental" and "thermal" sweating. Thermal sweating was least on the palms and the soles; greatest on the forehead, dorsum of hand, axilla, chest, and back. Mental sweating was greatest on the palms and soles, but occurred also on the forehead and face. Sweating was regulated by the sympathetic division of the autonomic nervous system, and control might be effected at cortical, hypothalamic, and spinal levels. The centre for thermal sweating was in the anterior hypothalamus and was stimulated by a rise in the temperature of the blood. The posterior part of the hypothalamus might regulate cutaneous vasoconstriction and shivering.

The situation of the centre for mental sweating was unknown, but the sweating was sudden in onset and increased quickly. Sweating occurred in certain mass responses—for example, shock reactions—but its usefulness in some of them was uncertain. The nerve endings to the sweat glands were cholinergic, and this had led Keele and Chalmers to look for some upset in the transmitter mechanism to explain hyperhidrosis. The response of normal and hyperhidrotic subjects to acetylcholine injected intradermally had been compared. Although hyperhidrosis might be due to the persistence of acetylcholine owing to some local deficiency of cholinesterase, or to hypersensitivity of the sweat glands themselves to acetylcholine, no evidence pointing to these possibilities was found. Hyperhidrosis was therefore attributed to overactivity of the centres.

Dr. R. E. BILLINGHAM (Birmingham), discussing the anatomical basis of epidermal pigmentation in man, said that melanin pigment granules were found in the deepest layer of epidermal cells, but obviously there were great differences in intensity of distribution between different races. The epidermis had two distinct types of cells: the basal-cell layer, from which by differentiation and keratinization the overlying layers were formed, and the dendritic cells. The latter were responsible for producing pigment. They could be demonstrated by separating dermis and epidermis by the tryptic digestion of small shavings of skin. If the digestion was prolonged the basal-cell layer began to come away and the processes of the dendritic cells were clearly shown. The dopa (dihydroxyphenylalanine) reaction had been applied to demonstrate the formation of dopa melanin in the dendritic cells, but the ordinary basal cells did not show it.

The processes of the dendritic cells ran upwards and horizontally between the round basal cells and ended as caps in contact with some of them. Almost every round cell in the basal layer was "capped," and the pigment granules within them had a polar distribution corresponding to the situation of the cap. In the upper layers the distribution of granules was random. It appeared that pigment was formed in the dendritic cells and transferred to the basal cells. In negro and Indian skin melanin was constantly being produced, but a definite stimulus, such as ultra-violet light, had to be applied to Caucasian skin to cause formation. It was suggested that there might be an inhibitor in Caucasian skin which was removed by the stimulus. The dendritic cells also supplied pigment to the hairs.

Dr. G. WEDDELL (Oxford), describing the pattern of cutaneous innervation, said that specific end-organs could be associated with certain sensations—Krause's bulbs with cold, Meissner's corpuscles with touch. A definite "spot" on the skin, a cold spot or touch spot, was usually related to a group rather than to a single end-organ. Nerve fibres corresponding to each organ left the region, which in this sense had multiple innervation. A hair bulb and hair might have two or three separate nerve fibres in which action potentials might be recorded.

Long-branching beaded processes were associated with pain, and they formed a network which might be the anatomical basis for the reactions on which Lewis based his hypothesis of the "nocifensor system." Disturbances in sensation at the margins of areas of local analgesia due to drugs, ischaemia, or nerve degeneration were thought to be associated with changes in the usual grouping of end-organs or the overlapping supply of the fibres subserving pain. The brain did not usually receive impulses derived from a single nerve ending, and normal sensation might depend upon the pattern of impulses projected on to the central nervous system.

SECTION OF NEUROLOGY AND PSYCHIATRY

Wednesday, June 29

Intractable Pain

Dr. J. PURDON MARTIN said that pain which had become intractable had ceased to be protective. Many cases of intractable pain were associated with lesions in nervous tissue—post-herpetic neuralgia, probably trigeminal neuralgia, causalgia, tabetic pains, the pains of syringomyelia, and the thalamic syndrome. In other cases nerves were involved in new growths. There was a partial lesion, or partial recovery of a lesion, of the pathways conducting painful impulses from the peripheral receptor fibres to the thalamus itself in a large proportion of cases.

A second group of patients were suffering from lesions affecting other structures, particularly bone. Pains might also reflect disturbances of function consequent on an organic lesion, as in angina or intermittent claudication. Pain was excited by a normal mechanism, which became unduly sensitive. The third group of cases, the most intractable, included painful neuroses, obsessional pain, and hysterical pain frequently affecting some part of the neck and tongue. Local operations aggravated the condition, and in Dr. Purdon Martin's experience psychotherapy had not proved helpful.

Surgical interruption of the conducting pathway between the site of the disturbance and the sensorium was applicable to all cases in the first and second groups, except the thalamic syndrome. It was still not known whether such cases could be relieved by an operation on the thalamus, or by prefrontal leucotomy. Prefrontal leucotomy was applied to the obsessional and hysterical cases. Medical treatment had not made any great advance. "Trilene" had a selective action on the trigeminal nerve. Morphine still retained absolute superiority in relieving pain. Pethidine and physeptone were in a lower rank, and pethidine might cause addiction.

Mr. WYLIE MCKISSOCK described the applications of spinothalamic cordotomy and prefrontal leucotomy. Spinothalamic cordotomy had proved highly successful in the treatment of intractable pain in the lower limbs and trunk as high as the fourth dorsal segment. In a total of 44 cases there were 36 successes, 7 failures, and 1 death; 6 failures were due to the low level of anaesthesia. The operation had been undertaken to relieve pain due to malignant growths (28 cases), neurofibromatosis (2 cases), painful flexor spasms (3 cases), and in one case each of osteoarthritis of the hip, spina bifida, post-herpetic neuralgia, abdominal pain, and intractable sciatica.

Intractable pain not extending much above the nipple line could safely be treated by section of the opposite spinothalamic tract at the level of the first to the third dorsal vertebrae. The operation was best performed under general anaesthesia in the sitting position—if the level of anaesthesia was not high enough the wound could be reopened in 24 hours to increase the extent of the cordotomy.

Mr. McKissock then described the details of the operative technique. Transient bladder disturbances which occurred post-operatively after bilateral section of the tract might prove permanent in patients with pre-operative changes in the bladder.

For intractable pain in the upper limb cordotomy was less successful. Intractable pain here was usually due to malignant growths, so that the operation of prefrontal leucotomy might properly be considered when other methods of treatment had failed. The results of leucotomy in a series of six cases had been good. Two patients had intractable thalamic pain, one post-herpetic neuralgia, three malignant disease. After operation the patients never spontaneously complained of pain; they were serene and required no drugs. The result was poor in one patient who required an extensive bilateral leucotomy. He became too apathetic to eat, and would not make a will before he died of carcinoma.

Dr. E. B. STRAUSS said that any discussion of pain raised the insoluble "body-mind" problem. An artificial distinction was often drawn between "real" and "imaginary" pain, despite the fact that all pain was in the final analysis a psychic event. Pain was an emotional as well as a sensory experience. Pain divorced from its emotional component was very different from the total experience, as was well shown by leucotomy. Severe pain which did not respond to analgesic drugs was likely to be psychogenic, or emotionally overdetermined. Many pains primarily psychogenic were secondarily somatogenic. Thus colic associated with a spastic colon would be innervated in the usual way through the autonomic system, although the spasticity might be psychically determined. Such states could be treated pharmacologically as well as psychologically at one and the same time.

Hypnosis was a much neglected reliever of pain. Hypnosis could be induced by the individual without a hypnotist or the mystical concept of *rapport*. Salter, in the United States, had elaborated methods of training people in autohypnosis which appeared to be sound and relatively simple. It was useful for an individual to be able to abolish existing pain at will, cure his insomnia, render himself deaf to disturbing noises, increase his inclination to work, and eliminate stage fright and other crippling forms of self-consciousness without dependence on any psychologist.

Dr. ANDREW WILSON (London) proposed to confine his remarks to the more recent work on analgesics. Although morphine enjoyed world-wide reputation as a pain-relieving drug, its other actions on the gut and respiration, and the possibility of addiction, severely limited its effectiveness. He outlined the attempts made to solve this problem by the preparation of derivatives of morphine—heroin, dilaudid, metopon, and also the pethidine series and the miadone derivatives.

He discussed the absorption of these drugs and the recent evidence that neostigmine increases the intensity and prolongs the duration of their action. The respiratory depressant action of these drugs was important, though some derivatives of miadone did not appear to exhibit this property.

All the analgesic drugs so far tested were potentially drugs of addiction, and consideration must be given to the factors of psychical dependence, acquired tolerance, and physical dependence. More critical methods of assessing the likelihood of addiction to new drugs were needed.

Dr. W. RITCHIE RUSSELL (Oxford) showed a film illustrating his method of treating painful amputation stumps by repeated percussion of the neuroma with a mallet and wooden applicator, as described in his recent paper in the *Journal* (June 11, p. 1024).

Dr. HUGH G. GARLAND (Leeds) discussed the part played by the sympathetic, and recalled that in India he had had many patients with causalgia. Some of these he had treated successfully by sympathetic block. The technique was to produce a temporary block by means of procaine at weekly intervals for three weeks. This was followed later by sympathectomy. More recently he had tried a similar technique for cases of post-herpetic neuralgia with some good results.

Dr. J. E. CAUGHEY (Auckland) said that the incidence of causalgia in the New Zealand Division in the war was small but his experience of sympathectomy was encouraging. He went on to discuss cases of cephalalgia. They usually presented with severe nocturnal unilateral pain associated with running from the eyes and nose. A similar pain could be induced in these patients by a subcutaneous injection of 1 ml. of histamine diphosphate. They could be desensitized by increasing doses of histamine diphosphate—starting with 0.01 mg. twice daily and ending with 0.5 mg. weekly. The headache tended to recur if the treatment was stopped.

Mr. W. R. HENDERSON (Leeds) drew attention to the distribution of organic and psychogenic pains. He said that in many cases psychogenic pain was in the distribution of a nerve and that the differential diagnosis was often very difficult.

Dr. MAX G. VALENTINE (Inverurie, Aberdeenshire) quoted recent reports on the value of unilateral lobotomy for intractable pain. Section on the side of the dominant hemisphere was particularly successful.

Dr. E. STENGEL (London) had noticed that in some hundreds of personally observed cases of psychological disorders treated by leucotomy there was no alteration in the response to painful stimuli apart from a general emotional indifference.

Dr. JAMES VALENTINE (Burley-in-Wharfedale) had seen some poor results following the surgical treatment of intractable pain. E.C.T. had temporarily improved some of his patients.

Dr. DOUGLAS GORDON-CAMPBELL (University of California) described the presence of damage to the occipito-atlantal joints revealed by tomography in cephalalgia due to head injury. Relief might be obtained by deep infiltration with procaine or by manipulation.

The President, Dr. W. RUSSELL BRAIN, described two cases: the first was a woman who had a glioma deep in the right parietal region involving the thalamus. A pin-prick on the left foot produced the typical thalamic overreaction. Pin-pricks simultaneously on both feet failed to produce this overreaction. This raised the most interesting possibilities concerning the part played by the cortex in the awareness of pain. The second case was a woman with carcinoma of the breast and secondaries involving her brachial plexus and causing severe pain. Leucotomy made her euphoric. There was some personality deterioration, but apart from that the result was strikingly good.

Mr. WYLIE MCKISSOCK, in reply, said that his patients, after leucotomy, perceived extraneous painful stimuli normally. He also said that leucotomy, as practised in this country, produced comparatively little personality change. This was probably due to the limited material of the operation as compared with that practised elsewhere. He advocated a technique for undercutting areas 9 and 10. This produced very little personality change and was effective in controlling the pain.

Dr. PURDON MARTIN, in summing up, remarked how the discussion had emphasized the close affiliation between neurology and psychiatry. He said that Professor Weiss, of Strasbourg, had given up leucotomy for intractable pain, except in people with a short expectation of life, because he had found that after a time the pain tended to recur. The problem of persistent post-herpetic neuralgia was particularly difficult because the patients were so often obsessional.

SECTION OF OCCUPATIONAL HEALTH

Wednesday, June 29

The Future of Occupational Health

The President, Professor R. E. LANT (Manchester), who was in the chair, opened the proceedings by stressing that in the present economic predicament this country could not afford to deploy its doctors unwisely. Medicine could exist in industry not as a luxury, but only as a service contributing to the health and efficiency of industry.

Dr. DONALD STEWART (Birmingham) said that a number of individuals and scientific groups believed that there was nee

for the expansion of occupational health services. The Prime Minister had recently appointed a committee to advise on the organization of these services so as to ensure that there was no overlapping with the National Health Service. As a basis of any plan for future expansion the aims and purpose of an occupational health service should be clearly defined, and these had been set out in a recent B.M.A. report (*Supplement*, May 28, p. 296). There were five main purposes. First, to attend to hygiene and environmental conditions. Secondly and thirdly, to assess fitness for work and provide for rehabilitation and resettlement. Fourthly, to provide for the emergency treatment of illness and injury. Here he said that too many medical officers were doing too much curative treatment, which in small units should be cut to a minimum. Fifthly, to promote research. With the reorganized Industrial Health Research Board this country was now pursuing industrial health research as never before.

The purposes could not be fulfilled without educating industrial medical officers on the lines adopted by Manchester University. The selection of these medical officers must be just and wise and satisfactory to all parties in industry. There should be a central authority planning the services. The Ministries of Labour, National Insurance, and Health all had claims, but of the three the Ministry of Health was the one he would choose. Within this Ministry there should be a small Department of Occupational Health, which should first appoint 14 regional consultants who would undertake surveys to find out facts on which the future services would be based. After regional surveys, suitable standards could be laid down and related to different types of industrial organizations. Legislation would be required giving power to force firms with no services or with substandard services to come up to these standards. Those firms already having their own services would be approved, provided their identical health services reached the required standard. Each organization should bear the cost of service with suitable allowances on an agreed basis with the Treasury.

Progress in the development of a national service should be slow and based on facts. It would be wise to start with a small administrative organization capable of expansion. The prospect would be gloomy if there was to be a rapid growth based on confused concepts. It would be foolhardy to rush into a national scheme without essential data.

Dr. STUART LAIDLAW (Glasgow) said that occupational health was a specialized branch of preventive medicine and had a basic relationship with public health. It was reasonable to advocate that the practice of occupational health could be undertaken by some of the larger local health authorities.

In Scotland there were twelve large cities or industrial counties in which over 90% of all its factories were situated. These authorities already had statutory duties and legal powers for factory supervision. In Glasgow two pilot investigations had been carried out in a weaving mill and in the Corporation cleansing department by medical officers attached to the Glasgow Public Health Department. It was shown that an efficient service could be provided for smaller units in industry by a public health authority with the assistance of general practitioners at little extra cost to the community.

Other arguments in favour of an occupational health service based on the major local health authorities were that the school medical and the industrial health services could easily be brought more closely together. The staff of the health department included impartial investigators who had access to and close liaison with other health workers in the local authority. Particular attention should be paid to providing health services for cafés and restaurants.

Dr. N. J. COCHRAN (Burton-upon-Trent) said that the employment of part-time general practitioners in factories offered a more practicable solution to the problem of providing a service for small factories than group services with whole-time industrial medical officers. Group service was impracticable for scattered factories partly because it entailed too much time spent in travel; and even for small factories in areas such as trading estates it was difficult for one doctor to make close contact with many employers and several groups of workers. Provision must be made for other working groups such as those in offices, laboratories, hotels, catering establishments, transport undertakings, etc., which all had both special and general occupational health problems.

The general practitioner with duties in industry could see both the industrial and domestic aspects of disease and ill-health. Dual responsibility of this kind would help to break down the barriers set up by specialization and would eventually be of benefit to the patient. Large industrial communities should have whole-time medical officers. The general practitioner working in industry could help to relieve the growing burden of sickness which weighed so heavily on the personal health services.

In the discussion which followed, Dr. ALICE STEWART (Oxford) said that decisions about new schemes should be postponed until more facts had been collected by the academic departments of social and industrial medicine, which were equipped to carry out selected field surveys.

Dr. E. H. CLUVER (Johannesburg, S. Africa) said that in his country gold-mining was the main industry with the predominant hazard of silicosis. It was now realized that nearly all the people were "occupied" and therefore subject to occupational hazards. In the reorganization of the training of South Africa's medical students it was proposed to pay special attention to social medicine, which would include occupational health.

Dr. W. BLOOD (London) stressed the dangers of increased mechanization, which made it almost impossible to place every worker in a job which satisfied his abilities. He considered that Dr. Laidlaw's work showed the need for increasing the size of the factory inspectorate.

Dr. F. S. COOKSEY (London) said that occupational health must be regarded under the headings of research, teaching, and field work. A central organization was necessary to stimulate research and teaching, but the responsibility for administering field work should be decentralized.

Concluding the discussion, Professor G. P. CROWDEN (London) said that the problems of occupational health called for co-ordinated team work. Before 1939 special intensive courses were organized for medical officers, safety engineers, personnel managers, nurses, and welfare supervisors. They met together and the spirit of co-operation was encouraged at an early stage of their training.

Several other speakers emphasized the importance of making the fullest use of general practitioners in any future scheme for occupational health services.

SECTIONS OF ORTHOPAEDICS AND RHEUMATOLOGY

Wednesday, June 29

Synovial Membrane

Under the chairmanship, first, of Mr. R. BROOMHEAD (Leeds), president of the Section of Orthopaedics, and, later, of Dr. W. YEOMAN (Harrogate), president of the Section of Rheumatology, Professor D. V. DAVIES (London) opened a discussion on the structure and function of synovial membrane. Synovial membrane, he said, was a relatively undifferentiated tissue forming the lining cells of the joint space developed within the embryonic mesenchymal condensation which became skeletal. Being undifferentiated in comparison with bone, cartilage, and ligaments, it had great powers of regeneration. But, being of the same mesenchymal origin, it was not surprising that under pathological conditions it might produce within it cartilage and bone. Its capacity to produce mucin strengthened the similarity to embryonic connective tissue. Its vascular structure influenced the formation and absorption of synovial fluid. The synovial cells were active in the removal of particulate matter from the joint cavity, as was well seen histologically when, after haemorrhage into the joint, those cells were found loaded with haemosiderin. The vascularity was increased at the edges of articular cartilage to form Hunter's vascular circle, which nourished the peripheral portions of that otherwise avascular structure. Except for the mucin, synovial fluid was a dialysate from the blood, and the addition of mucin admirably adapted the fluid to retention within the joint. The innervation of synovial

membrane was a controversial subject, and he supported Gardner's views that no free nerve networks or end-organs were found associated with the subjacent blood vessels. He had been able to prove in a living person that the membrane was insensitive to touch, pricking, and pinching; tugging, however, was soon resented, but the pain was not well localized by the patient and was thought to be due to more remote drag upon capsular ligaments.

Mr. D. ENGEL (Derby) said his own work tended to show that the [illegible] synovial membrane was diminished by inflammatory states and by lumbar sympathectomy.

Dr. D. H. COLLINS (Leeds), discussing varieties of pathological reactions in human synovial tissues, considered the pathological changes in synovial membrane under three heads: (1) Changes in synovial cells; (2) vascular and exudative phenomena; (3) leucocytic reaction. Under the first he emphasized the importance of histiocytic differentiation and phagocytosis, which were characteristic of haemarthrosis and were present in certain benign synoviomata. Such histiocytes might fuse and form the giant cells of a variety of pathological lesions. The vascular reactions of synovial tissues were often out of proportion to the severity of the inflammatory stimulus; the former was not infrequently maximal while the latter was minimal. Perivascular lymphocytic infiltration was slight in cases of chronic trauma and osteoarthritis. Massive infiltration was found only in severe chronic inflammation, and was particularly striking in rheumatoid arthritis; neutrophil polymorphic leucocytes were few, but it was noteworthy that in neighbouring joint effusions the proportion was reversed and they contained many polymorphs—probably because of their greater powers of motility. The rapid development and subsidence of these changes were well illustrated by the articular phenomena of rheumatic fever. Synovial tissues had a great capacity for repair and regeneration. These facts supported the views of Hench and his co-workers on the reversibility of joint inflammation, particularly in its less chronic forms.

Arthritis of the Hip-joint

Mr. H. PETTY (Leeds), discussing the denervation operation, reviewed the anatomy of hip-joint innervation. He had used partial denervation of the hip-joint in 19 cases. The results were encouraging. In three cases relief of pain was complete and in 12 was good, there being only occasional slight aching afterwards. Extraperitoneal resection of the obturator nerve was required, and division of the branch of the sciatic nerve to the quadratus femoris (the main posterior articular supply). The high division of the obturator nerve was justified because of the occasional high origin of articular branches and the advantage of denervating the adductor muscles.

Mr. R. BROOMHEAD (Leeds), after paying tribute to the work of Smith-Petersen, reviewed 100 cases of mould arthroplasty of the hip-joint which he had performed for a variety of conditions. Suitable cases must be medically fit and of a mental capacity to understand and co-operate in the pre- and post-operative regime. Age had little and sex no bearing on the result. The mortality was practically *nil*. The most important local factor influencing the result was the condition of the hip musculature. The best results were in patients with the most nearly normal muscles. The worst muscles were those fibrotic ones found in chronic rheumatoid and spondylitic hips, in which the results of arthroplasty were not good. He pleaded for the earlier consideration of arthroplasty by physicians in such cases, for surprisingly good results had been obtained in treating these acute forms of disease. Among other types of disease osteoarthritis gave the best results with this treatment. In young people those who had had early Perthes's disease or adolescent coxa vara did very well, those with spontaneous osteoarthritis not so well. In the largest group of cases—that is, of morbus coxae senilis—there was, as in all the others, freedom from pain and a range of movement which on the average was 40% of normal. Better results were obtained in patients with a long femoral neck. Deformity, particularly external rotation and flexion, added to the post-operative difficulties. One of the difficulties encountered after operation might be the formation of new bone, which might lock the cup in position and limit movement. It could be minimized by manual care while operating and by washing out all particles of bone dust.

Among the speakers who joined in the discussion Dr. DONALD WILSON (Bognor Regis) and Dr. G. D. KERSLEY (Bath) emphasized the soundness of Smith-Petersen's method of pre- and post-operative care—the training of muscles and the prolonged use of crutches. Mr. NORMAN CAPENER (Exeter), mentioning the unsatisfactory results of mould arthroplasty in ankylosing spondylitis, recommended Batchelor's procedure of excision of the femoral head and neck with a Schanz type of subtrochanteric osteotomy. This view was supported by Mr. F. W. HOLDSWORTH (Sheffield). Mr. H. JACKSON BURROWS (London) mentioned the effective method of hip-joint denervation practised through the Kocher posterior approach by his old teacher Elmslie in his operation of extirpation of the capsule.

Mr. BROOMHEAD in his reply agreed with most of what had been said, but, referring to arthrodesis for single osteoarthritic hips, warned against the possibility of osteoarthritis developing in the opposite hip.

Physical Treatment of Arthritis

Dr. H. F. TURNEY (London) said that whereas superficially applied heat was useful for the knee, short-wave diathermy was more suitable for the hip-joint. Exercises, which should be of non-weight-bearing type, were of particular importance for the restoration and maintenance of movement and for the muscular reconditioning which was of special significance in the knee, the stability of which was so dependent on its muscles. In all this work the Guthrie Smith apparatus, or improvised machinery of this type, was of great value. Active exercises were more important physically and psychologically than passively applied faradism. It was important to avoid fatigue. Reduction of weight by diet might be of value, but no particular diet benefited arthritis. The value of mud packs was in their poultice-like heating effect and not in the nature of their constituents. The beneficial effect of intra-articular injections was attributed to their acid content; he was not convinced of this in practice. Nevertheless such treatment was of great value; non-acid solutions could be used. Part of the benefit appeared to be due to the initial mobilization under local analgesia and the after-treatment. It should not be pursued indefinitely if no relief was obtained. Sometimes the results were dramatic.

Mr. GRANT WAUGH (Sunderland) believed the reactions of synovial membrane and their treatment had been much neglected. Because of the sensitivity of some of his patients to procaine he had given up administering this drug in his injections of lactic acid, the continued good results of which were independent of any local analgesic action. No other drugs were as satisfactory.

SECTION OF CHILD HEALTH

Wednesday, June 29

Common Feeding Difficulties in Infancy

A warm welcome was extended by the President, Emeritus Professor C. W. VINING (Leeds), to guests who included Dr. V. A. FENGER (Danish Medical Association), Dr. I. C. YUAN (World Health Organization), Professor C. C. DE SILVA (Ceylon), and Dr. D. G. CAMPBELL (San Francisco).

Professor R. S. ILLINGWORTH (Sheffield) contended that many of the difficulties arising in connexion with infant feeding were man-made and preventable. Routine regular test feeds might contribute to early failure of lactation by worrying the mother, by implying doubt about her ability to breast-feed, and by leading to the premature adoption of complementary feeds. Doctors, he thought, had a better knowledge of abnormal than of normal infant feeding.

Reviewing other common difficulties, Professor Illingworth deprecated the use of a fixed and rigid feeding schedule; drew attention to the undesirability of too strict insistence on a baby being put to each breast for ten minutes at each feed; stressed the danger of too much emphasis being placed on overfeeding; and commented on the effects of excessive clothing. Loneliness

gave rise to difficulties, and an infant should not be kept separated from the mother. A diagnosis of underfeeding required confirmation by test feeds before any question of taking a child off the breast was answered. Defective weight gain might arise as a result of defective intake, low-grade sepsis, or excessive clothing, or it might follow too literal adherence to "instructions on the tin" and too great reliance on the spoon as an accurate measure. Laxatives taken by the nursing mother were a not uncommon cause of diarrhoea in the infant, but in the breast-fed infant normal stools were often mistakenly described as loose, and stools normal in all respects might be described as constipated because of apparent infrequency.

Dr. CHARLOTTE NAISH (York) discussed common feeding difficulties in infancy from the point of view of the general practitioner. In assessing the value of breast-feeding it was misleading to compare "the underfed breast-fed baby" with "the fully fed baby reared artificially." Insufficiency of breast milk was an indication for complementary feeds and not for the termination of breast-feeding.

Study of 100 consecutive cases in general practice showed that circumstances (excluding accidents and notifiable infectious diseases) calling for domiciliary visits for babies of less than 1 year of age were much less common in the case of infants who had been breast-fed for an appreciable period than in those who had never been breast-fed or who had been breast-fed over only a short period. Morbidity was not influenced by social level.

There were among mothers "good, medium, and poor milkers." Too much must not be made of this fact, however. The likelihood of achieving successful breast-feeding was closely linked with the system of supervision. Often there were too many supervising authorities. Close contact with the patient must be maintained by the doctor. Breast-feeding must be discussed freely during the antenatal period, and continuity of supervision was essential. Portable scales were useful used in the third and fourth weeks at the time of the customary post-natal visits. Advice and supervision could be continued by the general practitioner at clinic sessions organized for this purpose.

Professor S. G. GRAHAM (Glasgow) dealt with problems related particularly to feeding of the premature infant. Feeding problems were inseparable from those concerned with the prevention and cure of disease in premature infants. Considering the smallest premature infants in the first few weeks of life, Professor Graham said that there was no evidence to justify the view that breast milk was not the milk of choice. Those who believed otherwise attached too much importance to gain in weight as the sole criterion of progress. There were other criteria, such as ability to feed, activity, and colour. The amount and technique of feeding were important. It was dangerous to stimulate these infants too early or too quickly. Oedema was common, and resulted from capillary damage due to anoxia and immature kidney function. Anoxia called for oxygen therapy. In the presence of oedema fluids should be withheld for at least 24 to 48 hours. Feeding by the bottle was desirable. Gavage and the use of a pipette involved a risk of aspiration pneumonia. The results of feeding the premature infant depended on the nursing staff.

Impressions based on a survey of 1,000 children attending infant welfare centres were given by Dr. E. BADENOCH (Birmingham). The children represented a random selection. Difficulties in infant feeding had not been eased by social factors related to overcrowding, housing problems, and queueing. While more mothers were attempting breast-feeding, fewer were maintaining it for six months. Difficulties in artificial feeding arose from the nature of "the instructions on the tin"; and from a tendency to give too few feeds. Habit vomiting was a fairly common source of trouble. Approximately 10% of infants are unable to take cod-liver oil in pure form, but they tolerated maintenance doses of concentrated vitamin preparations. Mild rickets was confirmed in 10 out of 2,000 babies examined in connexion with adoption proceedings. Common clinical conditions encountered were: pyloric stenosis under 2 months; gastro-enteritis and respiratory infection between 2 and 5 months; teething disturbance and otitis media between 5 and 8 months; and pyelitis between 8 and 12 months.

Mother-love was important, and the mother's daily presence was essential, and preferable to isolation in a nursery. Dried milks were the most favoured substitute for human milk in the lower-income homes, and have contributed to the reduced incidence of gastro-enteritis among infants.

Dr. J. MACKINTOSH (Birmingham) also stressed the importance of education beginning during the antenatal period. She suggested that local authorities might help family doctors undertaking antenatal care by lending local authority staff to provide the health education. In some instances use might be made of welfare and other centres.

Subsequent speakers raised a number of points. Professor C. C. DE SILVA (Ceylon) referred to the absence of feeding difficulties among the lower-income groups in Ceylon. He asked that the profession in this country should discourage the view common among Europeans that breast-feeding was contra-indicated in the Tropics. Dr. C. C. HARVEY (Doncaster) urged that greater attention should be paid to re-establishing breast-feeding prematurely discontinued. Professor A. E. NAISH (Sheffield) emphasized the value of test feeds, provided that the attendant was aware of variations within the normal range and provided that the mother had had explained to her the purpose and interpretation of the procedure. Test feeds at monthly intervals helped in the early detection of slight falls in milk supply which if uncorrected might contribute to undernourishment and anorexia on the part of the infant. Dr. POOLER (Chesterfield) said child-welfare experience confirmed the need for elasticity in education. The tenth day of the puerperium, when the mother resumed domestic responsibilities, was a danger period in lactation. Dr. SIMON (York) agreed that education for breast-feeding should start antenatally, regretted the multiplicity of foods available because they encourage unnecessary feeding changes, and commented upon the fact that adolescent schoolgirls thought of infants in terms of babies with bottles and teats. Dr. GOLDSBOROUGH (Leeds) said that changes in rationing and the national diet handicapped breast-milk secretion by depriving mothers of essential hormones of exogenous origin. In his experience only 10% of women are able to nourish their babies at the breast.

Dr. MARY CROSSE (Birmingham) shared views expressed previously concerning the value of breast milk for premature infants; suggested that there might be some advantage in giving extra protein to infants of birth weight under 3½ lb. (1.59 kg.); and said she had come across only one case of retro-lental fibroplasia in 3,000 premature babies. Dr. J. WEBB (Windsor) urged a review of teaching methods. Children's physicians and local authority medical officers should have more insight into each other's work. He emphasized the value of hospital breast-milk banks. Dr. S. KELSEY (Cheltenham) confirmed previous criticism of instructions on tins of artificial food. The basis should be expected weight and not age.

Summing up the discussion, Professor ILLINGWORTH stressed the need for knowledge of neonatal physiology; referred to the reduced risk of infection in breast-fed infants; and urged differentiation between overfeeding and wrong feeding.

Domiciliary Care of the Premature Child

Dr. F. J. W. MILLER (Newcastle-upon-Tyne) showed slides illustrating a domiciliary special nursing service at work in artisan homes in Newcastle. The service had been in operation since 1945. Of 244 premature infants born and nursed entirely at home 197 survived. Only 26 were admitted to hospital after receiving care from a home nurse. Assessment of the results was difficult. Comparing results with those obtained in premature units of the highest standard, it appeared that infants of birth weight over 3½ lb. (1.59 kg.) had as good a chance of survival at home as in hospital; and that the prospects of those under 3½ lb. were better in hospital. The value of the domiciliary service was threefold. It has a social value to the family, was a direct help to the family doctor, and facilitated the concentration of care on the very small infants accommodated in premature units.

In reply to questions Dr. Miller emphasized that the key to success in domiciliary care rested with the nurse and that ultimate clinical responsibility rested with the family doctor. Oxygen and electric blankets were supplied to these homes.

SECTIONS OF OBSTETRICS AND GYNAECOLOGY AND DERMATOLOGY

Thursday, June 30

Pruritus Vulvae

Professor T. N. A. JEFFCOATE (Liverpool) said that pruritus vulvae was a symptom for which approximately 10% of women consulted the gynaecologist. When patients complained of "irritations" of the vulva it was easy to assume that by this they meant "itching," whereas often they meant pain, tenderness, or a burning sensation. Unless there was a desire to mislead, the term pruritis should not be used. It was important to determine the site of the pruritus, for pruritus vulvae and pruritus ani often had different causes. It was also important to know if it was associated with pruritus elsewhere.

After discussing the mechanism of production of the sensation of itching, Professor Jeffcoate went on to consider the aetiology of pruritus vulvae. It might be associated with general pruritus, as in jaundice. Glycosuria was an important factor. Pediculosis gave rise to pruritus pubis rather than pruritus vulvae. His analysis of a large series of cases showed how many possible causes there were.

Causes of Pruritus Vulvae in 254 Consecutive Cases, Excluding Pregnant Women

	Number of Cases
Trichomonas vaginitis (not proved bacteriologically in 74, but clinically typical)	100
Chronic cervicitis, cervical erosion, and polypi	28
Trichomonas vaginitis probably present	9
Other factors present	4
Deficiency states	20
Vitamin B, deficiency	3
Achlorhydria	13
Deficiency anaemia (iron or liver factors)	4
Psychogenic causes	18
Skin diseases not specific to the vulva: psoriasis, intertrigo, intra-epidermal cancer, etc.	14
Prolapse	12
"Leukoplakia vulvae"	9
Glycosuria, diabetes mellitus	8
Fungus infection of the vagina and vulva	6
Senile vaginitis	6
Idiosyncrasy to chemicals (soap, "dettol," pessaries, contraceptives)	5
Allergic states	4
Post-menopausal atrophic vulvitis	4
Unknown	20

Professor Jeffcoate considered that one of the greatest advances of recent years had been the recognition that certain deficiency states could cause pruritus vulvae—for example, lack of vitamin A, B complex, and iron and liver factors. Probably 20% of cases were due to these deficiencies. He had details of 46 women with pruritus vulvae who had histamine-fast achlorhydria. They had been treated with dilute hydrochloric acid by mouth, and iron preparations when necessary, but no other general or local treatment. The results were:

Cured	34
Slight relief	1
Unknown	4
No response	7

The 34 cured cases were followed up, and it was found that 25 had permanent relief for one to eight years; one patient died of intercurrent disease; two were not traced; six had relapsed and did not respond to further treatment.

The most important part of the management of pruritus vulvae was a thorough investigation to find the cause. A careful history and full physical examination were required as well as (1) repeated examination of *fresh* vaginal swabs for trichomonas, *Oïdium albicans*, and other fungi; (2) a fractional test meal; (3) full examination of the blood; (4) a glucose-tolerance test; and (5) biopsy of vulval skin in selected cases. He concluded by stressing that even in the present state of knowledge a definite organic cause, amenable to treatment, could be found in not less than four out of every five women who complained of pruritus vulvae. In no more than 5% of cases was it impossible to give relief by one means or another.

Dr. G. A. GRANT PETERKIN (Edinburgh) pointed out that when a dermatologist diagnosed pruritus vulvae it indicated that there was no skin condition present to account for the itching, so that the case was either gynaecological or fell into the so-called "idiopathic" group, in a proportion of which the itching appeared to be entirely due to psychological causes. He thought that the highest incidence occurred between the ages of 30 and 39, and not, as was often thought, after the menopause. It was prudent to remember that venereal diseases could cause pruritus vulvae. He listed other conditions which might be responsible for pruritus.

Condylomata acuminata, when itching might precede the appearance of the warts by several weeks. Podophyllin resin was effective in these cases.

Flexural psoriasis, for which tar and ultra-violet light were best.

Lichen planus, which was often mistaken for leukoplakia, was best treated by the heavy metals, perhaps aided by *x* rays.

Lichen sclerosus et atrophicus was even more frequently diagnosed as leukoplakia. Carcinoma did not arise from the vulval lesions in this disease. Some cases responded well to prolonged treatment with stilboestrol ointment.

Contact dermatitis might be due to quinine pessaries, rubber contraceptives, clothing, medicated toilet-paper, sanitary towels, and even nail-varnish. The commonest cause of all was one of the myriad antipruritics prescribed, especially cocaine. The acute case responded well to treatment with starch poultices and Castellani's paint.

Drug eruptions—for example, those due to phenolphthalein and the sulphonamides—might cause pruritus.

Circumscribed neurodermatitis (*lichen simplex chronicus*) and the *asthma-eczema* group should be treated with crude tar, *x* rays and thorium X, or cod-liver oil and hydrochloric acid.

Flexural infective eczema could be cured by 1% gentian violet, and for *follicular infective eczema* treatment by means of a penicillin spray gave good results.

Fungus infections were due either to true ringworm or to yeasts, and were often found in diabetic patients. It had been pointed out that 18% of healthy women harboured monilia in the gastro-intestinal or genital tract. For fungus infections one of the best antipruritics was undecylenic acid.

"*Idiopathic*" *cases*, Dr. Grant Peterkin concluded, formed a group in which focal sepsis was often an important factor, as also were emotional and anxiety states.

Dr. C. J. MACKINLAY (Glasgow) said that monilial pruritus vulvae affected three groups of patients: the diabetic, the pregnant, and an "idiopathic" group in which no factor could be shown to be responsible for the continuance of the infection. Diagnosis was difficult, and he suggested that no gynaecologist should accept the diagnosis of a Grade I flora (Schroeder), particularly in cases of pruritus, unless swabs had been cultivated on Sabouraud's medium and had failed to grow colonies of fungus. A direct film stained by Gram's method might be most deceptive, as the fungus could assume a form morphologically indistinguishable from Doederlein's bacillus. Treatment by "mycil" pessaries and jelly had given satisfactory results.

Dr. ELIZABETH HUNT (London) said she had never seen a case of "idiopathic" pruritus vulvae. Pruritus was a symptom, not a disease. In her experience psychogenic causes were rare. She thought that "dettol" baths headed the list of irritants. She reviewed 88 cases referred to her for pruritus vulvae from January to June, 1949. The vulva only was affected in 34% of these cases, and in 4% the vulva was not affected at all. General constitutional diseases accounted for 20%, local affections 25%, skin diseases 50%, and other causes 5%. The present-day excessive carbohydrate diet might influence the condition.

Dr. E. LIPMAN COHEN (London) did not believe there was always just one cause for a disease. He thought the psychogenic factor was often primarily responsible in cases of pruritus vulvae.

Dr. F. F. HELLIER (Leeds) thought there was a lot of nonsense being talked at present about vitamin deficiencies

Hay fever CAN be relieved

Many cases of hay fever which have hitherto proved resistant to all forms of therapy, can now benefit from the symptomatic relief afforded by

trade mark **'ANTHISAN'** brand
mepyramine maleate

Failure to respond satisfactorily to 'Anthisan' is an indication for the use of the more powerful antihistaminic

'PHYTODERMINE' Cream and Dusting Powder

trade mark brand

for the prevention and treatment of fungous skin infections

Supplies: Cream — 1 oz. jars
Dusting Powder — 2 oz. canisters

'PHYTODERMINE' CREAM combines the anti-fungal activities of phenylmercuric acetate and terpineol in an elegant oil in water emulsion base which greatly facilitates penetration of the skin without making it unduly greasy. Salicylic acid is added as a reliable keratolytic agent. The final product is pleasant to use, non-staining and is easily removed by washing.

'PHYTODERMINE' POWDER contains a milder and completely non-toxic anti-fungal agent, methyl para-hydroxybenzoate, together with salicylic acid in perfumed talc base. It is designed to deal with those conditions which favour fungal infection — excessive moisture and friction — and the active constituent is usually adequate to check the development of the ubiquitous fungal spores.

The problem child . . .

THE problem child is frequently aided by 'Benzedrine' Tablets. Recurrent bouts of aggressiveness and destructiveness often yield to the drug in what appears to be a specific way. The noisy child becomes much more subdued; the activity of the hyperkinetic child becomes less disjointed; and co-operation, sociability, and behaviour are improved.

'Benzedrine' Tablets are often a useful adjunct in the treatment of nocturnal enuresis, particularly in cases that are characterized by unusually profound sleep.

● *Now available: 'Benzedrine' Ampoules containing 20 mg./1 c.c. for parenteral administration.*

'BENZEDRINE' TABLETS

Issued in bottles of 50 tablets each containing 5 mg. amphetamine sulphate

Dr. S. T. ANNING (Leeds) was sceptical about monilia causing colpitis.

Dr. BRIAN F. RUSSELL (London) said that psychogenic factors were most important. He believed that there were true deficiency states due to dietetic fads.

Dr. MURIEL KEYES (Harrogate) said many women were disinclined to go to their doctor when complaining of vulval itching. She stressed the importance of urethral disorders as a cause.

Others who took part in the discussion were Dr. A. BARKER (East Kent), Dr. G. A. HODGSON (Cardiff), Dr. S. L. NAVARATNAM (Colombo), Mr. J. A. CHALMERS (Inverness), Dr. S. SMITH (London), Dr. W. H. BROWN (Glasgow), Dr. H. R. VICKERS (Sheffield), Dr. A. FRENCH (London), and Dr. J. T. INGRAM (Leeds).

Summing up, Professor JEFFCOATE thought that all were agreed that pruritus vulvae was a symptom and not a disease. Vitamin deficiencies could exist without demonstrable deficiencies in the blood. Some 25% of women were carriers of trichomonas, and he wondered if this infection was not often spread in hospital wards.

SECTIONS OF RADIOLOGY AND CARDIOLOGY

Thursday, June 30

Angiocardiography

The Sections of Radiology and Cardiology combined for a discussion on "Angiocardiography," Sir JOHN PARKINSON presiding over the first part of the meeting and Dr. J. L. A. GROUT over the second. Sir John Parkinson said that this was the first occasion on which a Section of Cardiology had been arranged, and the cardiologists were glad that their first meeting should be with the radiologists, to whom they owed so much. They were also proud that one of their members, Dr. C. W. Curtis Bain, should be President of the Association.

Dr. FRANCES GARDNER (London) said that angiocardiography afforded a clearer understanding than had hitherto been possible of normal cardiac anatomy. In her department they had collected a small series of normal angiocardiograms in different age groups taken in the three standard positions used in fluoroscopy, and in addition to their educative value they had provided a useful standard for comparison with abnormal films. She proceeded to give a lantern demonstration of angiocardiograms in the normal child and adult and showed their value in the recognition of specific aortitis and in the differential diagnosis of aortic aneurysm and mediastinal tumour.

Perhaps the most striking contribution which this procedure had made to modern cardiology was in the realm of cyanotic congenital heart disease. The surgical procedures in this condition initiated by Blalock in the United States and by Brock in this country called for accurate anatomical diagnosis. The first concern in considering suitability for operation was to exclude those cyanosed patients in whom the pulmonary blood flow was adequate or increased. Here angiocardiography might only confirm the clinical diagnosis, but it might also add some useful anatomical details. Many abnormalities were included in this group, and for some of them surgery was contraindicated. The practicability of increasing the blood supply to the lungs depended on the presence of both right and left pulmonary arteries, and only by angiocardiography could this be determined with certainty.

Dr. J. WILKIE (Sheffield) sketched the earliest attempts to outline the cardiac chambers, culminating in the use by Robb and Steinberg of 70% "diodone." Many devices had been evolved for enabling a rapid series of radiographs to be taken. The most likely appeared to be some development of cine-radiography. He described a rotating cassette holder capable of giving six exposures at intervals of about 1 second. The position of the patient during examination was important. The arm must be maintained in proper relationship to the trunk during injection. Adults were examined under full sedation; children under general anaesthesia (cyclopropane). In the latter case a second injection could be made, provided an adequate interval was allowed between the two. Timing of the exposure intervals was correlated with the side of the heart which was suspect. He discussed possible dangers of the procedure, and referred to one isolated fatality. All possible care should be taken in the selection of cases, and the information likely to be obtained should be of sufficient value to justify the risk. He demonstrated the radiographs of four cases—coarctation of the aorta, complete transposition of the great vessels, Fallot's tetralogy, with early and late filling of the aorta, and pulmonary stenosis with an atrioseptal defect and rudimentary right ventricle.

Dr. K. D. KEELE (London) demonstrated the value of angiocardiography in seven cases, all in children with congenital defects. He described the history and signs in relation to the appearances in the angiocardiogram. In a case of patent interventricular septum, for example, the angiocardiogram showed filling of the right and left ventricles in 2 seconds, both remaining filled for 6–8 seconds. In a case of congenital heart block and patent ductus arteriosus the antero-posterior view showed a normal right auricle and right ventricle, poor filling of the left ventricle, small aorta, the pulmonary fields remaining filled for 8–10 seconds, and pulmonary clonus not filled at the same time as the aorta, while the left anterior oblique view showed patent ductus arteriosus. In a case of patent ductus arteriosus the angiocardiogram showed refilling of the left pulmonary artery from the aorta and, on an oblique view, a small localized dilatation of the inner wall of the descending arch of the aorta. The ductus was ligated, and an angiocardiogram repeated five weeks later showed now no refilling of the left pulmonary artery from the aorta, and the localized aneurysm of the inner wall of the descending arch of the aorta was larger than previously.

Dr. T. H. HILLS (London), whose paper was read in his absence through indisposition, said that Guy's Hospital had been fortunate in that a large number of cases in the cyanotic group had been investigated before operation, and the radiological findings had been checked in the operating theatre and at times in the post-mortem room. Angiocardiography was a dangerous investigation in this group, and should not be undertaken solely to confirm a diagnosis in a patient not suitable for operation. About 90 cases had now been *x*-rayed at Guy's. However well established a clinical diagnosis of Fallot might be, the thoracic unit at Guy's was not prepared to consider operation without this investigation. He discussed the technical requirements for the investigation. The films must be large enough to include the vessels of the neck, accurately timed so that correlation of the rate at which the chambers of the heart filled was possible, and taken at such intervals that there was not too great a difference between any two consecutive pictures in the series. Both antero-posterior and oblique views were of value, but if the diagnosis was in little doubt, and it was desired that the risk of a second injection be avoided, the antero-posterior view should be preferred. The oblique view, however, was desirable in a case of supposed ductus or a transposition. He went on to mention a number of points in the interpretation of angiocardiograms.

Dr. F. JACKSON (London) discussed present trends in North American clinics. Angiocardiography had been used at 157 different hospitals in North America, and in some 6,000 examinations. Three main methods were used: cassette-changing method, the continuous roll of *x*-ray film, and photofluorography, in which the fluorescent screen was photographed. At Mount Sinai Hospital, New York, where the greatest number of angiocardiograms had been taken (over 1,500), a gravity machine with electrically operated release was used. The continuous roll method had been developed at the Toronto Children's Hospital and at Ann Arbour. More rapid exposures could be obtained in this way, and many workers believed that the exposures made rapidly during the critical two or three seconds after injection revealed information not given by slower methods. It was believed that there could not be too many exposures in the early seconds. Photo-fluorography was difficult, chiefly because the fluorescent screen emitted only a small fraction of the energy falling on it as actinic light, and he did not think this method would provide a solution, at any rate for some time to come.

The subsequent discussion was chiefly concerned with the dangers of the procedure. Dr. FRANCES GARDINER mentioned some additional points. Some children had been examined while under sedation only, and she did not think that if the sedation was heavy enough the children suffered. Dr. J. WILKIE, on the other hand, insisted on general anaesthesia for children. Dr. E. JACKSON said that at Mount Sinai there had been no death in the 1,500 examinations, and this compared well with Johns Hopkins, but at the latter hospital a great number of very serious cases had been investigated. Dr. G. M. HAYWARD described how at St. Bartholomew's, where between 50 and 60 cholecystographic examinations of children had been carried out, anaesthesia was used, and, moreover, it was insisted that a most expert anaesthetist be employed, usually the anaesthetist who would act at the subsequent operation. Sometimes the patient might be under the anaesthetic for 1½ to 2 hours. There had been no fatalities, and since the use of sedation had given place to anaesthesia these cases had caused much less anxiety. Dr. F. T. FAULKNER (London) said that there had been two fatalities among the cases at Guy's. The first was after gas-and-oxygen anaesthesia, which was unsuitable, and the second was in a case where two injections were given, the second one to take an oblique view, with only 20 minutes' rest between the two. Cyclopropane was the anaesthetic of choice.

SECTIONS OF CHILD HEALTH AND PREVENTIVE MEDICINE

Thursday, June 30

Behaviour Difficulties in Childhood

Overseas visitors at this combined meeting included Lieut.-Col. J. W. REGAN (U.S.A.), Dr. E. H. CLUVER (South Africa), Dr. P. MORAN (Eire), Dr. I. C. YUAN (World Health Organization), and Dr. R. E. ANDERSON (Malaya). The chair was taken by the president of the Section of Preventive Medicine, Professor R. H. PARRY (Bristol) and later by Professor W. S. M. CRAIG (Leeds).

Dr. MILDRED CREAK (London) commented on the controversial nature of the subject and emphasized the need for attention to the preventive aspects of work at child-guidance clinics. She stressed the importance of history-taking and the dependence of successful treatment on lengthy first interviews. There should be closer contact between children's physicians and psychiatrists. An almost insoluble problem was that arising from the unwillingness or inability of parents to make necessary adjustments to the presence of children. Emotional problems could be traced to tension and conflict, which might be at the conscious level or might consist of influences carried over from deeper levels. Prevention could begin in the antenatal stage and be continued during the puerperium. "Rooming-in arrangements," which found favour in American maternity hospitals, were to be commended. They helped the mother to learn what her child wanted and they tempered the attitude of the staff.

One result of the small families of to-day was that adolescents learned little of home life and acquired only a limited experience of children. In our modern way of living, home-making and parentcraft came low in the list of priorities. The effects of the war years were evident among children who did not know their fathers in their earlier years. There was evidence that persisting problems were most common in children who had been evacuated and particularly in those who were evacuated when very young. There was a danger in removing a child from the emotional attachments of his home at certain stages in development. Divorce resulting in loss of a parent was a growing problem as a cause of difficulty in adjustment in children. Short periods in hospital could produce profound disturbances. Aggression in a child in hospital or at school might be a healthy attitude providing evidence of readiness to face and grip new problems.

Speech, reading, and number concepts had an orderly pattern of development. Confusion occurred on returning to school after an absence. Hospitals, she thought, should provide some form of educational help.

Dr. Creak referred to the unique opportunities possessed by welfare clinics if time was spent on first interviews; the importance of not being too ready to sacrifice a mother's warm care of an only child in order to place the child with others of his own age: and she urged the closer association of staffs of hospitals and school health services. More people were having fewer children, and so the child was in danger of being offered greater freedom in a world less ready to receive him. Physicians must try to reinforce the ties inherent in stable family life.

Professor C. W. VINING (Leeds) gave "spoiling" as the most common reason offered for behaviour problems. In fact attempts to avoid spoiling a child might give rise to unhappiness. Behaviour problems more often than not were the result of the imposition of a parent's will. The child needed love and affection from those looking after him. Forcing produced rebellion, negativism, and insecurity, where what was wanted was the promotion of courage, confidence, and freedom. Obedience to repressive measures was neither lasting nor natural. Single incidents did not have prolonged disturbing effects, whereas persistence in a parental attitude not understood by the child did. Spoiling might take many forms, including exaggerated anxiety, undue concern about happiness and well-being, and excessive interest in the natural bodily functions of the child. Most children attending hospital clinics were not suffering from underlying physical disease. The doctor must not encourage a wrong attitude in the child by too long a period in hospital, severance from education, or prologed convalescence. The importance of behaviour problems must not be exaggerated. These problems had wide implications related to common sense, public health, and education.

Dr. W. S. MACDONALD (Leeds), who was introduced to the Section as a family doctor, justice of the peace, and chairman of a juvenile court, referred to children reflecting their parents, to the influence of the mother being vital, and to the importance of the father being limited only by the amount of security he could give the mother. The tempo as well as the scale of juvenile delinquency was on the increase. Only 1% of all children became delinquents in a court sense, and in these cases only 10% called for action in the home. Delinquency was eight times more common among boys than among girls. A point of unquestionable importance was the religious point of view characterizing the family background. Too much emphasis could be attached to physical defect. Low intelligence-engendered a desire in the child to push himself forward if his school was unsatisfactory. Frustration developed and behaviour problems resulted.

Dr. MacDonald urged that education authorities should give the same attention to emotional stability as to intellectual advancement. The general practitioner should aim at enabling people to do without the doctor; and the mother should aim at keeping her child away from the child-guidance clinic. Child-guidance clinics should keep the child away from the juvenile court. Future preventive measures should pay special attention to girls of school-leaving age, too few of whom were conscious of the part they would play in the character formation of their children in the years ahead.

Dr. D. HENDERSON (York) drew attention to the important part to be played by the family doctor in prevention, and recommended closer linking of the child-guidance with other child-health services. Certain published assessments of the extent of the problem of behaviour disorders had probably exaggerated the real problem.

Dr. A. A. E. NEWTH (Nottingham) pointed out that as early suspicions about child guidance were being dispelled a balanced outlook was being established. Contact between hospital physicians and parents was to be encouraged. So also was a closer liaison between school health and hospital services. Psychiatric treatment for the child and the parent should not be undertaken by the same organization. Better treatment facilities for children were required. The influence of school on the child was not fully appreciated. Schooling might give rise to difficulties, but more frequently served as a valuable corrective to the feeling of insecurity due to tension in the home.

Dr. MARGARET LOWENFELD (London) said that children should have the reasons for their admission to hospital

explained to them; that greater importance should be attached to the place of food in the imagination of the child in hospital; and that new hospital design should take more account of a child's psychological needs. The view that religious bodies and local education authorities should take a more active part in tackling delinquency was advanced by Dr. H. SUGARÉ (Leeds). The point was made by Dr. CHARLOTTE NAISH (York) that the family doctor should aim at establishing an attitude of understanding friendship towards the mother, utilizing the opportunities of general practice to further education for health. Dr. D. D. PAYNE (Harrogate) suggested that reference of pupils to a child-guidance clinic should be by the school medical officer. There was need on occasion to protect children from teachers who were enthusiastic about psychology and ready to refer too many children for examination. Organic disease was considered to be a common source of behaviour problems by Dr. W. N. LEAK (Winsford). Dr. F. P. H. BIRTWHISTLE (Barton-on-Humber) argued that children should be told what they should do and not what they should not do, and stressed that threats of correction did more harm than good if not followed by action when indicated.

Dr. P. MORAN (Eire), contrasting the position in his own and in this country, attributed the existence of behaviour problems to an ever increasingly complicated social structure, to emphasis on group existence to the detriment of family life, to failure to appreciate the advantages of isolation, and to lack of emphasis on moral and religious considerations.

Summing up, Dr. CREAK agreed that newer ways of thinking involved risks of a wrong conception that ideologies might replace humble belief in ourselves. She said the value of the father in a child's life was derived from the adventuresomeness and the loving authority of his personality. She gave a reminder that where there was a choice the average person preferred to be physically ill rather than emotionally ill.

Tuberculosis and other Conditions in Childhood

In the afternoon members of the Child Health Section paid a visit to Scotton Bank Sanatorium, where Dr. VINCENT RYAN (Knaresborough) demonstrated an interesting series of patients and radiographs.

OTO-RHINO-LARYNGOLOGY

Thursday, June 30

Nasal Allergy

With the president, Mr. A. B. PAVEY SMITH, in the chair, Mr. R. R. SIMPSON (Hull) opened a discussion on nasal allergy. He gave figures showing the incidence of the condition, and thought that the apparent increase was really due to increased recognition of it. It was merely a local manifestation of a constitutional condition. Treatment should be fundamental and not simply a local palliative. The characteristic nasal picture was described, and compared with that of so-called sinusitis. Nasal polypi were predominantly allergic in origin; 97% of his cases showed marked eosinophilia.

In non-seasonal allergy skin tests were of some use in children, but not in adults.

Specific desensitization was sometimes satisfactory, if temporary, in children, but useless in adults. He discussed the antihistamine drugs, and nicotinic acid given in addition. Local applications to the nose should be isotonic with the nasal secretions and not over 1% in strength. He deprecated ionization, cautery, sclerosing injections, and x-ray treatment. Radium was useful only for the prevention of recurrent polypi. Surgery had little or no place in the treatment of non-infected cases.

Professor R. B. HUNTER (Dundee) described the effects of antihistamine drugs in perennial vasomotor rhinorrhoea. All cases studied had allergic mucosa diagnosed by biopsy, and the standard of cure was the return of mucosa to normal, again as judged on biopsy. All cases were first given dummy tablets for 14 days. During this period 5% were cured. Of the remaining cases, 54% were cured after one month's treatment with "anthisan," and nearly two-thirds of these were still symptom-free after 15 months. It would be well worth while to try to estimate the amount of histamine present in nasal biopsies and determine whether this was in direct proportion to the number of eosinophil cells present.

Mr. J. GERRIE (Aberdeen) discussed allergy in children, which had been increasingly recognized by paediatricians in the last decade. Unfortunately the general public still expected the condition to be cured by removal of tonsils and adenoids. It was important to diagnose and treat allergy in the early stages, and to avoid all treatment which might tend to add infection. He stressed the importance of family history and past history.

A small biopsy was the most reliable diagnostic aid. In treatment general measures were proper sleep, exercise, light and airy clothing, and avoidance of the specific allergen. He had found non-specific desensitization quite valueless and specific desensitization good but troublesome. For local treatment cauterization had given the best results, followed by breathing exercises for a month. Elixir of "benadryl" was useful, and "anthisan" in older children. Operations should be performed only if there was infection, or if there was obstruction by adenoids.

Dr. LEON UNGER (Chicago, U.S.A.) disagreed with Mr. Simpson on the value of skin tests. He thought that 50% to 70% of cases of perennial allergy gave a positive skin reaction, particularly to house dust. He divided cases into three groups: (1) seasonal, due to pollens; (2) seasonal or perennial, due to fungi; (3) perennial vasomotor rhinorrhoea. Three factors were present: (1) constitutional, usually hereditary; (2) contributory, such as fumes, dust, temperature change; (3) exciting allergens. The presence of more than 4% of eosinophils in the cell count of nasal smears was diagnostic of allergy.

Treatment should be preventive, and by desensitization. Probably 75% to 80% of all so-called "sinusitis" was due to allergy. Purulent material from sinuses should be stained and examined: it might then be found full of eosinophils. House dust probably contained some specific factor, the dust from bedding and upholstered furniture being much more potent than that from carpets. Local nasal treatment should not be prolonged. Antihistamine drugs were of some value. Surgery should be reserved for cases of marked polyposis, severe septal deviation, sinus infection, and septic tonsils and adenoids.

Dr. H. HENDERSON MOLL (Leeds) thought that non-seasonal vasomotor rhinitis was often not allergic, but caused by nervous and non-specific factors. Allergic rhinitis, however, was a frequent accompaniment of allergic asthma, and the changes observed in the nose reflected the general allergic condition. Allergy was suggested by the age of onset (under 40), by a positive family history, and, in a high proportion of cases, could be confirmed by skin tests. Nasal polypi occurring with asthma usually pointed to an infective factor. They occurred in an older age group, and were normally associated with infective asthma. The effect of administering para-amino benzoic acid, 100–500 mg. every two hours during the day, was described.

Dr. D. R. BELLETTY (Assam), as a sufferer from nasal allergy, described the failure of submucous resection, followed by improvement later with desensitization and the use of a vaccine. Mr. A. S. DE B. COCKS (Adelaide, South Australia) thought that in house-dust allergy skin tests were positive in almost all cases, and that polypi were usually of allergic origin. Dr. S. F. L. DAHNE (Reading) found that in cases of so-called catarrh or nasal obstruction about 20% of adults and 25% of children were allergic. Dr. J. G. REED (Malaya) asked if varying nasal obstruction was due to allergy. Had any serious side-effects been produced by antihistamines? Was there any scope for psychiatric treatment in children?

Mr. R. SCOTT STEVENSON (London) deprecated the suggestion that operations were harmful, and stressed the importance of the surgeon's deciding whether an operation was indicated. Nothing gave more satisfactory results than submucous resection in the proper case. Dr. KATE MAUNSELL (London) asked if the combination of antihistamine drugs with desensitization was harmful. Dr. S. DEBONO (Malta) thought that any surgery would give temporary relief, but that the condition would recur. Therefore it was best avoided.

Mr. E. R. Garnett Passe (London) said he did not find that turbinectomy or excision of the sphenopalatine ganglion had any effect on vasomotor rhinitis. Mr. Pavey Smith (Harrogate) emphasized the importance of prevention. The duration of efficacy of antihistamine drugs was not known. Increased incidence of polypi among farm workers seemed to be associated with the increased use of dusty chemical fertilizers.

Mr. Scarborough said in reply that points which should be noted were the appearance of the turbinates, the presence of the clear septum, small uninfected tonsils, and normal tympanic membranes, together with a past and family history of allergy.

SECTION OF OPHTHALMOLOGY

Thursday, June 30

Eye and Skin

Dr. James Fison (Harrogate), president, was in the chair, and, during the afternoon, Mr. A. B. Nutt (Sheffield), vice-president. Mr. J. H. Dobart (London), opening a discussion on ophthalmology in relation to diseases of the skin, pointed out some of the ways in which the two specialties overlapped. He deprecated the overtreatment of styes, but emphasized the importance of not neglecting blepharitis. Maladies which implicated the outer coat of the eyeball were considered, with special reference to ocular rosacea, pemphigus, and other vesicular diseases. He also discussed skin lesions associated with disease of the anterior uveal tract, with cataract, and with fundus disturbances, illustrating his remarks with pictures.

Dr. Alan Carleton (Oxford) discussed the vesico-bullous diseases, some of which were known to be caused by viruses. Although wide variations in severity were encountered in practice, and although the immediate or precipitating factor was by no means constant, yet the pathological changes in the epidermis were essentially the same in that group of conditions. The term "aphthosis" had been advocated to embrace such vesicular eruptions, and it would appear that, under the influence of certain noxious stimuli, liquefying epidermal cells released enzymes which interfered with the mechanism of carbohydrate metabolism, so that the tissue was asphyxiated.

Dr. I. B. Sneddon (Sheffield) stressed the association of ocular and dermal abnormality in disorders of development as well as in allergic reactions. It was important to search for localized dermatitis of the legs or other remote regions in cases of unexplained blepharitis. He emphasized the part played by endogenous and exogenous toxins in the production of that disorder. His own clinical experience strongly supported the generalizations made by Klaber and Wittkower (*Brit. J. Derm. Syph.*, 1939, 51, 501) on the typical personality of patients with rosacea.

Dr. N. McAlister Gregg (Sydney, New South Wales) supported the principle of therapeutic simplicity, and testified to the value of hydrogen peroxide and liquor tinctorium in the treatment of blepharitis. Mr. A. G. Cross (London) suggested that it was far easier to cure one particular attack of blepharitis than to prevent recurrence of this condition. Mr. A. G. Palin (Bristol) advocated cleansing of the eyelids twice daily with a face-flannel as a precautionary hygienic measure, but Mr. Doggart subsequently pointed out the dangers of using a piece of material so liable to be contaminated. The unfavourable influence of septic teeth and seborrhoea of the scalp on the eyes and the eyelids was emphasized by Mr. H. M. Jay (Adelaide). Mr. H. G. W. Hoare (Newport, Mon.) mentioned certain disadvantages of penicillin therapy.

Scleromalacia Perforans

Mr. H. V. Ingram (Newcastle-upon-Tyne), discussing scleromalacia perforans, said that the association of that rare disease with polyarticular arthritic disturbance was not invariable. He reported two cases, one of which had derived benefit from operation. Dr. N. H. Ashton (London), who had collaborated with Mr. H. V. Ingram in the investigation of his material, raised the question whether there might be a relationship between scleromalacia perforans and certain cases of brawny scleritis.

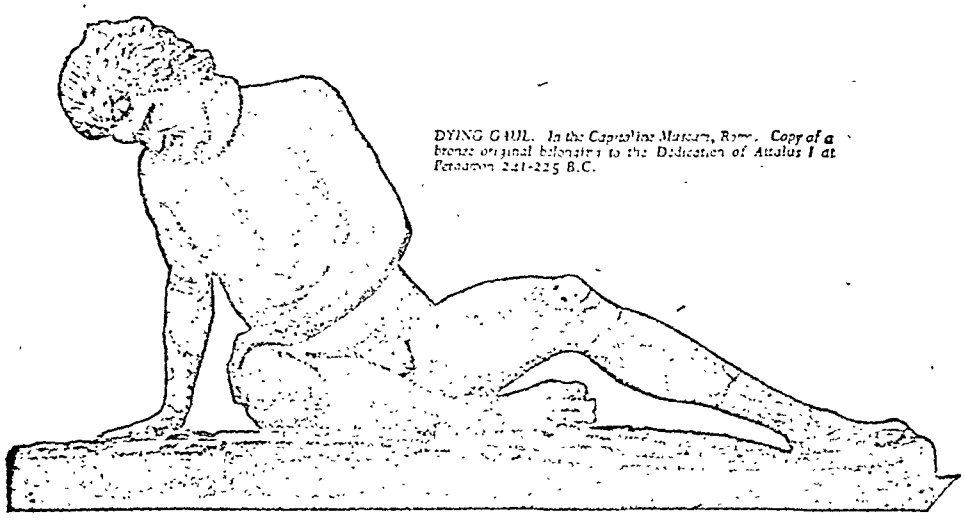
Angiomatosis Retinae

Mr. A. G. Cross (London), discussing angiomatosis retinae, briefly surveyed various congenital and acquired conditions which might simulate the von-Hippel–Lindau syndrome. Only a minority of cases would display the complete range of intracranial and visceral lesions in association with the characteristic ophthalmoscopic changes. The latter consisted of localized tumours supplied and drained by enlarged vessels, together with exudates near these masses, or at the macula, or in both situations. Both eyes were affected in about one-third of the cases, and multiple tumours were often evident. Familial incidence had been repeatedly noted. As angiomatosis retinae was a progressive disease, early treatment was necessary. Diathermy and radiotherapy often gave the best chance of arresting it. In neglected or unsuccessfully treated cases retinal detachment usually supervened, and was accompanied or followed by uveitis, complicated cataract, and finally phthisis bulbi. Haemangioblasts, which were the characteristic cells, were capable of forming solid cords as well as elaborate reticulations and adventitious vessels, and the outer walls of the arteries leading to angiomatous retinal masses were usually thickened of distinguishing between retinal arteries and veins in advanced cases of von-Hippel-Lindau's disease. Dr. N. H. Ashton (London) asked Mr. Cross whether he had ever seen malignant metastases arising from these retinal tumours. Mr. Cross replied that he had not.

Mr. A. J. Ballantyne (Glasgow) referred to the difficulty

Watery Eye

Mr. N. P. R. Galloway (Nottingham), vice-president, emphasized the multiplicity and variability of the nerve supply to the lacrimal glands, and reviewed the physical, chemical, and emotional factors which could influence the flow of tears.



Mr. Doggart and Dr. N. McAlister Gregg cited examples of lacrimation being provoked by various foodstuffs. Dr. Gregg also pleaded for early probing in cases of infantile mucocele of the tear sac. Mr. R. I. T. Lloyd (Bradford) suggested that the long course taken by the fifth and seventh cranial nerves, together with their variable relationship to the sympathetic filaments, obscured the problems of lacrimal secretion. He hoped that light would be thrown on the question by further research into the functions of the hypothalamus.

SECTION OF PREVENTIVE MEDICINE

Friday, July 1

Pregnancy and Tuberculosis

With Dr. R. H. H. Jolly (Wolverhampton), vice-president, in the chair, a discussion on marriage and pregnancy in relation to tuberculosis was opened by Dr. F. A. H. Simmonds (South Mimms). He said that a wide range of opinion existed as to possible risks to the partner; it depended on how far latent lesions were included in surveys. The influence of poor social and economic circumstances was paramount. Probably there was a really, but not excessively, higher incidence of the disease in the consorts of the tuberculous. Married women in general had more favourable mortality rates for tuberculosis than single women. Women whose disease was controlled should not be refused permission to marry. Investigation showed that patients with the disease quiescent who became pregnant remained as well as other women of the same age and circumstances; where active disease was present, no convincing evidence was obtainable that pregnant patients fared worse. Artificial termination of pregnancy was not without its dangers; it should be employed with care and discrimination only when strong indications were present in the individual. In general, patients should be instructed to avoid pregnancy till the disease had been quiescent for two years at least. Marriage and children had a vital place in normal life for a woman and should not be forbidden except for the strongest reasons. The well-being of tuberculous patients depended much more on their natural and acquired resistance, on their economic and hygienic circumstances, and on their happiness in personal relationships than on the prevention of marriage and pregnancy.

DYING GAUL. *In the Capitoline Museum, Rome. Copy of a bronze original belonging to the Dedication of Attalus I at Pergamum 241-225 B.C.*

Shall he expire?

Severely injured and undernourished patients require a diet which will restore a positive protein balance without delay. It is not sufficient to give protein in amounts equal to those lost, for unless carbohydrates are provided to meet the total need for calories, the protein is merely used as fuel to meet the energy demands. Hepovite, which is a balanced mixture of essential amino acids, readily digested carbohydrates and vitamins, is ideal for the treatment of those combined deficiencies where protein, calories and vitamins are required.

Hepovite

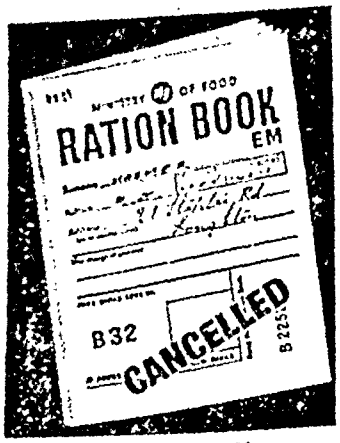
"MESONTOIN"

A marked advance in the treatment of

EPILEPSY

GRAND MAL, JACKSONIAN & PSYCHOMOTOR ATTACKS



Mesontoin offers considerable advantages over other hydantoins, in that the incidence of side effects is low, the dosage may be maintained at a high level, and that more effective control is obtained in resistant cases

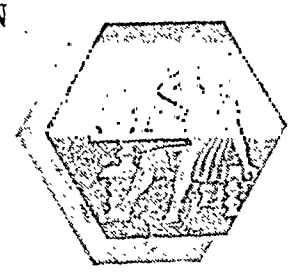
UNFINISHED STORY

The treatment of Habitual Abortion



'PROLUTON'
INJECTION OF PROGESTERONE B.P.
1 cc. ampoules of 2 mg., 5 mg., 10 mg. and 25 mg.

It is quite true that progesterone therapy frequently fails to prevent abortion since there are various other factors which may be responsible. Recent clinical reports, however, indicate that the most common single cause of habitual abortion is progesterone deficiency. In such cases adequate substitutional therapy with 'Proluton' enables pregnancy to continue to term.

'PROLUTON'

BRITISH SCHERING LIMITED
167/169 GREAT PORTLAND STREET, LONDON, W.1

DE GUSTIBUS NON DISPUTANDUM EST (*Pr.*)

Taste cannot be disputed

The need for iron in cases of pregnancy and post-partum anaemia is generally recognised, yet the form in which it is given must depend on the individual needs of the patient.
Taste cannot be disputed—but a prescription for only three 'Plastules'—daily will be found readily acceptable to the patient. They are easy to take and contain ferrous iron in semi-fluid form, sealed fresh in a gelatin capsule. Thus a rapid response without causing digestive upset is achieved.

PLASTULES

Each Plastule Plain contains Ferrous Sulph. Exsicc. B.P. 5 gr., dried yeast ½ gr. They are also available with hog stomach, with liver extract, and with folic acid.

JOHN WYETH & BROTHER LIMITED

ALUDROX - BEPLEX - ENDRINE - PETROLAGAR

Wyeth

Dr. R. C. COHEN (Braintree) said that provided adequate supervision and treatment were available the results confirmed the view that there was no evidence that pregnancy, labour, and the puerperium had any harmful effect on the course of tuberculosis. It was doubtful whether there was a strictly clinical justification for termination of pregnancy, though social factors might justify such a measure.

Dr. JEAN HALLUM (Birmingham) said that tuberculous women, even with severe lesions, gave birth to healthy but often premature babies. Stillbirths were not increased. When prematurity was allowed for, the figures for neonatal deaths showed no increase. The total infant mortality, however, was high (105 per 1,000 live births), the chief cause of death being gastro-enteritis, with which was associated the high prematurity rate, lack of breast-feeding, and risk of infection attached to residential nurseries. As regards the mothers, primigravidae fared worst, especially when the lesion was not diagnosed before pregnancy.

Dr. C. J. STEWART (Colindale) said that exceptionally a patient might be allowed to become pregnant. Prognosis was little different between pregnant and non-pregnant cases. Some deaths and relapses occurred after delivery.

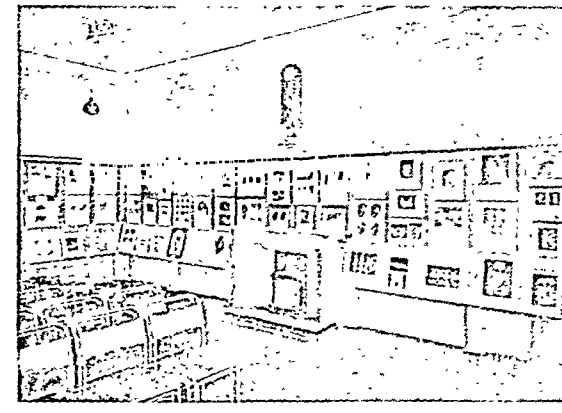
Dr. E. D. IRVINE (Dewsbury) criticized the suggestion that termination of pregnancy might be justified because of social difficulties—present or future. It indicated a failure in public care, and not least in the health service. Dr. H. J. TRENCHARD (Harrow) said that the risk of infection depended more on the resistance of the healthy consort (i.e., tuberculin-negative reaction) than on any other factor. Dr. D. I. MART (S.E. Essex) asked what advice should be given to a tuberculous married woman if she was anxious to have children.

Dr. R. C. COHEN (Braintree) replying to Dr. Irvine, said it was difficult to justify artificial termination on purely clinical grounds. Any strain there might be after delivery was largely due to worry, extra work, or financial anxiety. It was possibly the duty of the State to help in that respect. The possibility of infection in domestic workers suggested that they should be tuberculin-tested. In reply to Dr. Mart he advised against pregnancy in active cases and until after two years' quiescence.

Dr. F. A. H. SIMMONDS (South Mimms) in replying stressed the importance of using all known preventive measures to control the risk of infection to those in contact with tuberculous persons—affianced, consorts, domestic helps, and children. These included routine radiological examination of contacts, tuberculin-testing of infants, children, and young adults, and, when available, the use of B.C.G. vaccination. In the meanwhile removal of babies from the tuberculous environment was important; breast-feeding was permissible only when the disease in the mother was proved quiescent.

Recent Developments in Influenza

With Dr. D. D. PAYNE (Harrogate), vice-president, in the chair, Dr. C. H. ANDREWES, F.R.S. (Hampstead), read a paper on recent advances in the diagnosis and treatment of influenza. Laboratory diagnosis of influenza, he said, was unimportant from the point of view of treating the individual patient. However, it was vitally important to identify the causative agent of outbreaks in order to help our understanding of epidemiology and prospects of control. Recent diagnostic methods included (1) isolation of the virus from throat washings, (2) haemagglutination tests, and (3) complement-fixation tests. The two former had to be done on pairs of samples taken in the acute stage and again in convalescence. Vaccines of high potency could be obtained by purifying and formolizing virus grown in fertile eggs. Their efficacy in preventing influenza had been proved where a homologous strain of virus was concerned. It was not only a question of the two influenza types A and B; there were serological races within the A group differing sufficiently to affect the results of attempts at prophylaxis. Strange antigenic types of virus might spread from one country to another. The epidemiology of influenza must therefore be studied on a world-wide basis.



Dr. J. E. CAUGHEY (New Zealand) said that in Auckland they had had an epidemic of influenza which started 18 months ago. The diagnosis had been established by serological tests with antigen (A and B) received from Professor Burnet. Both A and B strains had been present and in some cases A and B combined. There had been four deaths, and the secondary invaders in these cases had been penicillin-resistant strains of *Staphylococus aureus*. Four cases had presented as primary atypical pneumonia.

MEDICAL PHOTOGRAPHY

EXHIBITION IN LONDON

An exhibition of medical photography by members of the Medical Group of the Royal Photographic Society of Great Britain was opened at the Society's headquarters of 16, Prince's Gate, London, S.W.7, by Sir Cecil Wakeley, chairman of the Medical Group, on July 4. The exhibition is open from 10 a.m. to 5 p.m. until July 16. The accompanying photograph (taken by E. V. Willmott, F.R.P.S.) shows one side of the exhibition room. The first exhibition arranged by the Medical Group was held a year ago, and it is hoped that next year's exhibition will include photographs from members in the Dominions and Colonies.

At this exhibition the emphasis is mainly on the clinical appearance of a lesion, though there are many fine photographs of pathological specimens, such as No. 85, "Aortic Valves in Rheumatic Carditis," from the Manchester Royal Infirmary.

Another interesting photograph from the same hospital is No. 93, "Rheumatic Tendon Nodules." Among the many good photographs illustrating clinical appearances are the following: No. 21, "Acromegaly," and No. 23, "Osteoclastoma of Hard Palate," from the Middlesex Hospital; No. 22, "Squamous-cell Carcinoma of Tongue," from the Royal Cancer Hospital; No. 10, "Clubbing of Fingers," from St. Bartholomew's Hospital; No. 11, "Psoriasis of Nails," from the Westminster Hospital; No. 18, "Nodular Tertiary Syphilis," from St. Mary's Hospital; No. 40, "Mediastinal Obstruction" (an infra-red photograph showing venous congestion), from the Postgraduate Medical School; No. 67, "Acid Erosion of Teeth," from the Manchester Royal Infirmary; No. 96, "Osteomyelitis—Cross Leg Skin Flap," from the Royal National Orthopaedic Hospital. These are only a few of the 150 exhibits.

Photographic Assessment of Therapy

There are some conditions which it must be hard for a photographer to record, but very realistic results can be achieved—for example, two photographs of the skin in avitaminosis (No. 89, by Dr. A. C. Roxburgh, and No. 94, from the Postgraduate Medical School). A method of using photographs to assess progress during therapy is illustrated in No. 47, "Spondylitis Ankylopoietica," from the Manchester Royal Infirmary. About fifty of the exhibits are coloured transparencies. Three new motion pictures are also included in the catalogue of the exhibition: "A Case of Gross Involuntary Movements," by Mr. C. E. Engel; "The Multiple Pressure Technique of Vaccination," by Dr. B. Stanford; and "Ankylosing Spondylitis," by Dr. P. Sattin.

Reports of Societies

FUTURE OF MEDICAL OFFICERS IN THE FORCES

At a meeting of the United Services Section of the Royal Society of Medicine on June 28, Sir HENRY TIDY presiding, a discussion took place on the professional future of the medical officers of the fighting forces.

Air Marshal P. C. LIVINGSTON, opening the discussion, briefly outlined the personal qualities that the successful Service medical officer should exhibit at different stages in his career. Surgeon Commander P. G. BURGESS, R.N., said that the naval doctor now obtained some experience in treating women in the W.R.N.S. and children in the families of Service men, but he required more help to keep his professional knowledge up to date. He suggested there was a place for the non-specialist on the staff of naval hospitals, and that specialists should give teaching rounds in the wards and out-patient departments for the benefit of medical officers in port. After his initial commissions at sea and in a shore establishment the young surgeon lieutenant should spend a period in a naval hospital; if he proved his ability, he should have the chance to study for higher degrees.

Speaking for the Army, Major A. D. YOUNG said there must be considered first the requirements of the Service, and secondly the ambition and ability of the individual officer concerned. The general duties officer was as essential to the Service as his specialist colleague, for he achieved familiarity with military administration, tactics, and planning. Major Young suggested the early selection of suitable general duty officers for training for future staff rank.

Group Captan F. E. LIPSCOMB maintained that the general duties medical officer must be afforded certain opportunities. He should be able to render useful service to the R.A.F. as a doctor; to lead a professionally satisfying life; to reach a position of responsibility, authority, and reasonable reward; and on military retirement to compete for employment on an equal footing with other doctors. He added that all careers in a fighting force must be subordinated to a primary aim of that force: the preservation of health in readiness for war. The general duties officer should be encouraged to widen his professional experience and to take greater responsibility in treating his own patients without frequent reliance on the specialist. Group Captain Lipscomb thought that medical administration should be regarded as a specialized subject which could provide a career for many general duties medical officers. It was impossible to offer a full career in clinical medicine in any Service for a non specialist.

Surgeon Lieutenant-Commander L. D. ARDEN, R.N., pointed out the disparity in the recognized value of the general duties medical officer and the specialist. He thought conditions of service could be improved and the officer should take a course and an examination before promotion to the rank of Surgeon Lieutenant-Commander.

Major J. C. BABBAGE said the general duties medical officer was the general practitioner of the Services; he should hold a definite tenure of appointment as a regimental medical officer and attend courses in professional and military subjects. Early specialization among medical officers should be discouraged.

Squadron Leader J. B. LOUDON proposed that conscription of medical officers should be abandoned in favour of the enlistment of more regular officers.

Surgeon Commander T. CRAWFORD said that the administrator, as well as the specialist, must be trained for his post.

A comparison between the lives of a doctor in the fighting forces and his civilian counterpart was made by Major A. BENNETT. He said that the Service medical officer enjoyed a congenial life with opportunities for travel, and regular hours of work. He had ample equipment for treating his patients, and consultants were always available. He also had the chance of postgraduate specialization. The civilian doctor, on the other hand, could expect more family life, a greater variety of clinical medicine, and higher remuneration.

Surgeon Lieutenant-Commander J. GLASS suggested a programme of training for the general duties naval medical officer during the first 15 years of his service. He said that the first course should be held on entry to the Service. It should be concerned with naval organization and health problems. The second course, to be taken after five to eight years' service, should last for nine to 12 months; it should consist of a study of medicine, surgery, public health, administration, and marine medicine. After 12 years' service further instruction should be given to qualify the officer for the rank of surgeon commander. This should resemble the second course, but with emphasis laid on administration. A final course in recent advances in medicine should be held after 15 years' service.

Sir HENRY TIDY, summing up, said that the Services must make the best of the medical officer of average ability as well as the better man. The general duties medical officer would benefit from hospital appointment early in his Service career, and should be offered repeated opportunities for postgraduate study (not necessarily with the aim of his becoming a specialist) to preserve his interest in clinical medicine. He should be allowed to retire if he saw no chance of his advancement after the age of 35. Sir Henry added that it was impossible under present conditions to abolish the conscription of medical officers.

BRITISH ORTHOPAEDIC ASSOCIATION

The spring meeting of the British Orthopaedic Association was held at Nottingham on April 22 and 23. The papers were presented at Nottingham University; the clinical part of the meeting was held at Harlow Wood Orthopaedic Hospital. The value of the meeting was enhanced by the presence of five Canadian and ten American orthopaedic surgeons who were paying a six-weeks visit to orthopaedic centres in this country. Those from Canada were Drs. F. P. Patterson (Vancouver), W. B. McKinnon (Winnipeg), F. P. Dewar (Toronto), R. Gariepy (Montreal), and J. A. Leo Walker (Montreal), and from the U.S.A. Drs. J. H. Allan (Philadelphia), C. B. Larson (Boston), L. R. Straub (New York), Hugh Smith (Memphis), S. B. Fowler (Nashville), B. E. Obletz (Buffalo), J. J. Fahey (Chicago), W. H. Bickel (Rochester), V. T. Inman (San Francisco), and D. W. Blanche (Los Angeles).

Upper Limb

Dr. VERNE T. INMAN (San Francisco, California) illustrated experiments showing that elevation of the upper limb involved rotation of the clavicle about its long axis, and that fixation of the clavicle to the coracoid prevented elevation above shoulder level. In eight patients the clavicle had been completely excised without loss of function, except that holding things above the head required extra effort. This operation was suggested as an adjunct to arthrodesis of the shoulder for joint disease.

Mr. TOM ROWNTREE (London) considered anomalies in the innervation of the hand muscles, referring to 688 cases of median- and ulnar-nerve lesions treated at the Wingfield-Morris Orthopaedic Hospital, Oxford, and at the Royal National Orthopaedic Hospital, London. Cases with known complete axonal division had been accepted—102 of median-nerve lesion and 124 of ulnar-nerve lesion. The observations were checked in a few cases by procaine block of the unaffected nerves. The lumbricals were ignored because of the difficulty of assessing their power, and flexor pollicis brevis was described as one muscle. Of these subjects 33% showed the innervation ordinarily described in the textbooks, the median nerve supplying abductor pollicis brevis, opponens, and flexor pollicis brevis, and the ulnar supplying adductor pollicis, the hypothenar muscles, and all the interossei. The flexor pollicis brevis had a purely ulnar supply in 32% and a clinically demonstrated dual (median and ulnar) supply in 16%. The normal arrangement was, therefore, that abductor pollicis brevis and opponens were supplied by the median nerve, and the adductor pollicis, interossei, and hypothenar muscles by the ulnar; the supply of flexor pollicis brevis was variable and probably usually dual. An anomalous supply was found in 20% of patients, including some with complete

median innervation and some with complete ulnar. In a few cases procaine nerve block had demonstrated an anastomosis between ulnar and median nerves in the forearm. These results emphasized the fallacy of diagnoses based on muscle power alone.

Dr. S. BENJAMIN FOWLER (Nashville, Tennessee), discussing the extensor apparatus of the digits, stated that the extensor communis tendons had no insertion into the proximal phalanges of any functional significance. The inability of extensor communis to extend the interphalangeal joints of the claw hand depended upon hyperextension of the basal joints. If these had capsules tight enough to prevent hyperextension in cases which otherwise would show claw hand the interphalangeal joints could be actively extended by the long extensor tendons.

Mr. R. G. PULVERTAFT (Derby) demonstrated tendon surgery in the hand with a motion picture. Among the procedures shown were shortening of the dorsal expansion in old cases of mallet finger, repair of the boutonnière lesion of the extensor expansion, tendon transplantation of extensor indicis proprius for rupture of extensor pollicis longus, suture of divided flexor tendons of the fingers, and their replacement by tendon grafts.

Mr. DAVID TREVOR (London) described five cases of spontaneous rupture of extensor pollicis longus tendon after Colles's fracture treated at intervals of one week to five months after rupture. He had bridged the inevitable gap with No. 6 nylon (non-capillary) sutures. Good union had occurred. The sutures had been removed three months or more after operation. Rupture was ascribed to aseptic necrosis from ischaemia. Mr. BRIAN L. MCFARLAND (Liverpool) suggested that ischaemic changes in the tendon might be caused by strangulation in the pulley opposite Lister's tubercle.

Mr. E. MERVYN EVANS (Birmingham) put forward clinical and experimental evidence that the anterior Monteggia fracture was caused by a combination of forced pronation and longitudinal compression of the forearm. In full pronation the radius and ulna crossed in contact, and continuing forced pronation would break the ulna near its middle and prise the radial head forwards out of its joint. Closed reduction by supination had succeeded in nine out of eleven cases. Mr. F. W. HOLDSWORTH (Sheffield) confirmed Mr. Evans's observation that "compounding" of this fracture was always forwards. He treated children conservatively, but in older people the ulna might be plated. Excision of the radial head gave bad results. Sir REGINALD WATSON-JONES (London) said that one form was clearly due to direct injury—the "baby-car" fracture or, as the Americans more picturesquely put it, "the side-swipe" fracture. There might still be a place for plating the ulna, but not for open reduction of the radial head. Mr. W. SAYLE-CREER (Manchester) doubted whether supination alone would maintain reduction, which was sometimes prevented by the rent capsule.

Lower Limb

Mr. P. C. ELMES (Oxford) had analysed the results in 115 cases of fractured neck of femur treated by closed nailing and followed up for two years or more. The clinical results were good in 35 cases, fair in 42, and bad in 38; in three of these repinning was successfully carried out, in six unsuccessfully. Anatomical results were estimated in 61 cases radiographed more than two years after operation. Sound bony union had occurred in 39 cases, but nine of these showed ischaemic necrosis with collapse of the femoral head. Established non-union was found in 22. In men fractures of the femoral neck were as common before 55 years of age as after, but in women they were much commoner after that age.

Mr. R. C. MURRAY (Inverness) discussed the classification and results in 100 consecutive patients with trochanteric fracture of the femur treated conservatively by simple weight traction combined with a medial-rotation bandage, early movement being encouraged. Ten patients, aged over 80, died. The anatomical results in the others were: excellent 33; good 29; fair 21; bad 7. The functional results were: excellent 25; good 42; fair 14; bad 9. Apart from patients who had already had spastic paralysis before fracture, the fair or bad results had been mainly due to prior osteoarthritis of the hip. With ordinary nursing skill conservative treatment was best.

Mr. WILLIAM GISSANE (Birmingham) referred to 44 consecutive patients, of an average age of 75, with trochanteric fractures treated by the Capener–Neufeld nail. Of the 32 who had completed treatment 31 had a normal or excellent range of movement in hip and knee.

Dr. L. R. STRAUB (New York) gave the results in 80 cases of lumbo-sacral fusion by Dr. Philip Wilson's method, in which metallic fixation was combined with the Hibbs procedure supplemented by bone chips, both autogenous and from the "bank." One patient had died of post-operative shock. Of the remainder, 69 showed solid bony fusion on radiological examination in various positions at the end of six months; failure in five had been at the lumbo-sacral joint, and in five at a higher level. Recently, metallic fixation had been combined with a cortical graft, and 25 patients out of 27 had shown solid fusion. Among 103 patients treated without metallic fixation there had been three deaths and 29 failures.

Mr. J. ROLAND HUGHES (Preston), discussing the radiological diagnosis of recent lesions of the lateral ligament of the ankle, recalled that avulsion of a bony flake was exceptional, but diagnosis of ligamentous injury by radiography of the ankle with the foot inverted was now well established. He had carried out this examination on 90 consecutive injured ankles and 90 normal ankles. About 6° of tilt represented the transition from normal to abnormal. The lateral ligament was lax with the ankle plantar-flexed and tight with it dorsi-flexed. In the cadaver, important tilting did not occur until the anterior talo-fibular ligament was cut, and the capsule also as far as the lower limit of the articular surface of the talus. Tilt through 30° was then possible. These ligaments were torn by a movement of plantar flexion combined with rotation about the medial malleolus. If tilting occurred through 18 or 20° or more there must be rupture of the anterior talo-fibular ligament, the calcaneo-fibular ligament, and the intervening capsule. The anterior talo-fibular ligament was the first to give way.

Mr. J. GRANT BONNIN (London) considered that tilting up to about 15° indicated rupture of the anterior talo-fibular ligament; 15–30°, the calcaneo-fibular ligament also; more than 30°, all three parts of the ligament. It was important to radiograph the opposite talus, which could be tilted about 4° in 10 to 15% of cases.

Mr. NORMAN W. ROBERTS (Liverpool) discussed osteochondritis dissecans of the elbow. The condition was almost confined to the male, was commonest under the age of 15, and affected both elbows in perhaps a quarter of cases. A diffuse cystic change was frequent. The loose bodies, if detached, were much more often multiple; irregular or ragged lesions were commoner than in the knee. The radial head was usually enlarged, and premature epiphysial fusion might occur. An association with preceding injury was difficult to establish. Radiographs of cases of loose bodies in the elbow very often revealed flattening of the capitellum and pronounced enlargement of the radial head, evidence of an unsuspected origin from osteochondritis dissecans rather than from osteoarthritis, which was often a complication rather than a cause. Mr. H. JACKSON BURROWS (London), said that the presence of bone in the separated fragment was important in distinguishing between osteochondritis dissecans and chondromalacia, which was often mistaken for it.

Professor J. DELCHEF (Brussels), discussing nerve-root pain of vertebral origin not dependent on disk prolapse, emphasized that such conditions as apophysial sprain were real entities and that arthritis of the posterior articulations might be an important cause of sciatica of single root origin. Mr. J. R. ARMSTRONG (London) recalled that the first sacral root, the most frequently affected, was unrelated to a posterior joint, and furthermore that sciatica was not usually relieved by arthrodesis. Almost all cases were due to intervertebral disk lesions.

At a special meeting a transatlantic club was formed, to be known as the A.B.C. Club, representative of its American, British, and Canadian members. The main function of the club is to facilitate similar visits in the future and to concentrate, as far as possible, the work and material to be seen.

BIRMINGHAM AND MIDLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY

At the Birmingham Medical Institute on March 31 the final meeting of the Midland Obstetrical and Gynaecological Society was held under the chairmanship of the president, Mr. W. E. BARNIE-ADSHEAD. It was decided to wind up this society and to found a new society to be called the Birmingham and Midland Obstetrical and Gynaecological Society. Professor HILDA LLOYD was elected president, Mr. H. C. MCLAREN is the secretary, and Mr. SAMUEL DAVIDSON the treasurer.

Mr. H. R. DEVAL, Mr. L. M. PARK, and Mr. A. WENTWORTH TAYLOR were also elected as additional members of an interim committee to formulate the rules of the society.

Dr. C. E. PURSTOW, who was the first secretary of the former society in 1912, was invited to become an honorary member. It was also decided to invite former members of the old society to become foundation members of the new society. An informal luncheon was held at the Queen Elizabeth Hospital, after which the members proceeded to a clinical meeting in the Medical School. Two papers were read: one by Professor HILDA LLOYD and Messrs. W. E. BARNIE-ADSHEAD, P. J. GANNER, and C. W. TAYLOR on "Masculinizing Tumours with Pregnancy Following Their Removal," and another by Mr. H. C. MCLAREN—"Control of Menopausal Symptoms by α-Tocopherol."

SCOTTISH SOCIETY OF THE HISTORY OF MEDICINE

On June 18 a party of members of the Scottish Society of the History of Medicine made a pilgrimage to places of interest in connexion with four sons of Scotland famous in the annals of medical history. Dr. Douglas Guthrie, president of the Society, led the party, which visited the grave and library of William Smellie at Lanark. Thereafter homage was paid to the memory of David Livingstone when the Livingstone Memorial at Blantyre was visited. The party then went on to the farm of Longcalderwood, East Kilbride, near Glasgow, which was the birthplace of the brothers William and John Hunter.

NORTH OF ENGLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY

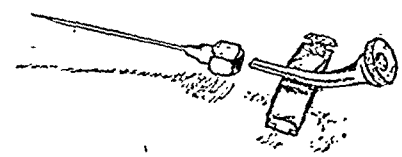
The president, Mr. S. B. HERD, of Liverpool, took the chair at a meeting of the North of England Obstetrical and Gynaecological Society held in the Royal Victoria Infirmary, Newcastle-upon-Tyne, on June 17.

Mr. H. HARVEY EVERS described a case of melanoma of the cervix in a spinster of 62 who had complained of slight pink "spotting" twelve years after the menopause. The patient had an atrophic vagina, which made examination difficult, but under general anaesthesia a small vascular shallow ulcer without pigmentation was seen on the vaginal cervix. Unexpectedly this was shown on section to be a melanoma. The patient made an uninterrupted recovery following a Wertheim hysterectomy.

Mr. BRYAN WILLIAMS gave an account of a case of full-time ectopic pregnancy delivered at laparotomy a month after the death of the foetus. The placenta was not removed, and severe haemorrhage was controlled by oxidized cellulose.

Miss C. M. GREY reported a case in which a granulosa-cell tumour of the ovary was associated with an adenoacanthoma of the body of the uterus and was successfully treated by radical operation. Mr. S. MADDEN described a case of chorionepithelioma arising from the Fallopian tube in a patient who had previously had a tubal mole. Finally Mr. T. G. ROBINSON discussed the value of pre-operative penicillin in combating uterine and extra-uterine infection in cases of carcinoma of the cervix.

INTERNATIONAL BOOK EXHIBITION



It would be fair to say that British book production can compete with any in the world. In Oslo, for example, British books—and British medical books in particular—make a magnificent showing in the bookshops surrounding the university. Yet a visit to the National Book League's Third International Exhibition of Book Design, on view till July 23 at 7, Albemarle Street, London, W.1, gives the impression that British books are sorry things. This is certainly not due to the amount of space given to them, which is greater than that given to any of the other countries exhibiting. But it is very difficult to see on what basis the selection of books was made. The art books look very well, though not so well as they deserve; the children's books are also good. Other sections fall far below standard, and technical books are extremely badly represented. There are no medical books as such, but there is one on biological assay, the general appearance of which is ordinary. Other countries have included in their more limited number of exhibits excellent technical books, and beautifully produced medical textbooks are shown by Norway and by Holland. The price of admission, 2s. 6d., may put off the casual visitor; the catalogue is extra.

Preparations and Appliances

AN IMPROVED GORDH NEEDLE

Dr. F. L. ROBERTSHAW, Obstetric Registrar, Moorgate General Hospital, Rotherham, writes: The British version of the Gordh non-clotting intravenous needle was described in the *British Medical Journal* (1947, 2, 834). Briefly, it consists of a needle to which is attached a rubber diaphragm. Injections are made through this diaphragm, which prevents reflux of blood into the needle, the latter remaining patent even after a few hours in a vein. The device is especially useful in techniques involving repeated injections of thiopentone and curare, since it avoids the need for an intravenous drip or repeated venepuncture.

As at present supplied, however, the Gordh needle suffers from two drawbacks. First, the needle is too big for small veins, so that haematomata may result from attempts to use it. Secondly, it must frequently be resharpened if it is to enter veins easily. To overcome these drawbacks I have modified the usual Gordh needle by removing the original needle and fitting in its place a standard Record needle fitting. Any needle can now be fitted to the device and replaced when blunt. I have found a size 15 hypodermic needle most useful: with this the device is equally suitable for young children and smaller veins. In addition, the venepuncture can be carried out either with an unmounted needle or with one attached to a syringe, and the device attached when the needle has been well placed in a suitable vein. All the advantages of freedom from clotting are retained, and in addition the smaller needle reduces the risk of haematoma and a sharp point is always available.

The original modification was made by me from a standard Gordh needle and a Record fitting derived from an old one-way tap. The instrument here illustrated has been made by Blease Anaesthetic Equipment, Ltd., 223/227, St. John Street, London, E.C.1. Thanks are due to Mrs. C. Ballantine for the accompanying diagram.

The Ministry of Transport has recommended that a sulphonamide dressing for burns and wounds be included in the Merchant Shipping Medical Scales instead of the picric acid dressing.

Correspondence

Mind, Machine, and Man

SIR,—I feel sure that all of your readers must have been as fascinated as I was by Professor Geoffrey Jefferson's Listerian Oration on "The Mind of Mechanical Man" (June 25, p. 1105). Here we have an example of medical philosophy at its best, for it is a philosophy with its feet firmly on the ground. Perhaps one of the most fundamental points to which he draws attention in comparing the brain with the modern computing machine is the tremendous difference in complexity—ten thousand million brain cells as compared with twenty thousand valves of the American or one thousand of the more economical English machine—factors of 500,000 or 10,000,000 respectively.

To think of, say, a million such machines (the coverage area would give the Ministry of Town and Country Planning cause for anxiety) all properly integrated is beyond the imagination of my 10,000,000,000 cells. But the actual disparity would be much greater than this, for it appears that the brain cell, unlike the electronic valve, is capable of responding to more than a single type of stimulus—e.g., electrical, chemical, physical, and so on. To all of these and their combinations and permutations a nerve cell may react, and so the factors given above must be still further increased. Even if a supermachine were constructed in the future capable of responding to other than electronic impulses, the lecturer reminds us that it would have no self-consciousness, no ego, and so would not be a brain in the truest sense. Those holding completely mechanistic views concerning the relationship between brain and mind would nevertheless probably agree that this shortcoming is more than a mere question of greater, but similar, complexity. Our perception of our own consciousness remains a riddle to-day, despite all the thought that has been given to it throughout the ages.

But so far I have been using your valuable space for a simple paraphrase of Professor Jefferson's remarks, and this was not my intention. I think the lecture provides an analogy to, and a warning concerning, certain tendencies which we see all around us. I was particularly impressed by the author's repeated admonition that we should not allow ourselves to be led away by the specious suggestions that here we have in effect a model of the brain in action, and that we should not "anthropomorphize the machine." Rather should we emphasize the great differences (not only in complexity) between the brain and the machine, otherwise we may fall into the error—common enough nowadays—of believing that because we are able to plan, build, and control the machine we are capable of producing a blue-print of the living brain accurate enough to be put to practical use. I have no objection to the production of a blue-print as an academic exercise, but I have the strongest antipathy to any attempt to apply it, in our present ignorance, to the control of human destiny.

I am afraid that my lack of facility in the handling of words has obscured the issue, and so I fall back on a practical example to make myself clear—at least so I hope. The present population of this country is stated to be some 50,000,000 units, which, although much less than the 10,000,000,000 cellular units of the brain, is nevertheless a vast number. Each unit has its own individuality and its own responses to the stimuli of its environment. Each presents a much greater variation of activity than that of an individual neuron. And so our society, considered as a whole, has as much complexity of organization and variability of response (social and political) as the brain has in its particular sphere of action. Yet we have people in no small number who believe that a blue-print of our social and political life can be drawn up, and who furthermore act upon such a blue-print in advocating what is called a planned State. They appear to have no conception that the meagre information and statistics upon which their plans are based bear no more relationship to the complexities and interactions of social life than does the mechanical computer to the real human brain. Would we permit the clever designers of the electronic computing machines, because of their knowledge, skill, and diligence in that field, to control the whole of our psychological and nervous life?

The reason why I have the gravest doubts, both rational and intuitive, of the planned State is that I do not believe we have at present anything like sufficient knowledge of the intricacies and complexities of social behaviour to warrant interference except in the simplest matters. As doctors we have had a good example of the unpredicted effects of the application of planning during the past year. He would be an incorrigible optimist or a bigoted ignoramus who regarded the outcome as anything more than an extremely disappointing exhibition of the unforeseen vagaries of human reaction under changing circumstances. But planners, possibly intoxicated by the magnitude of their plans, seem to see nothing wrong; and in any case humanity is very adaptable—there is always a considerable time lag before the effects of a change are fully felt and appreciated, and collective mankind has a short memory.

Our own profession's problems are, however, only a small part (probably smaller than we are apt to think) of the general problem which now affects the whole nation. Because mankind can successfully plan houses, Mulberry harbours, atomic bombs, and other mechanisms, the planners, with complete disregard of the enormous difference in complexity between even an atomic bomb and the social organization, audaciously step in where angels fear to tread and force us to accept their plans for our happiness, our desires, our ambitions, and the whole of our destiny.

From Professor Jefferson's lecture we learn to regard with great suspicion any attempt to explain the complexities of thought and psychological action by comparing the brain with the infinitely simpler computing machine. Equally we should be supremely cautious in applying our meagre knowledge of simple social reactions to the extremely complex problems of sociology. Surely it behoves us to regard the question with great humility, not with overweening arrogance. Certainly we should hesitate and hesitate again before taking any action based on our theories which will affect the lives of our fellow men. Let us not be lured from our scientific agnosticism by the facile talk of the planners, for they know not what they do.—I am, etc.,

London, W.1. NORMAN C. LAKE.

SIR,—I should like to stress that the problem of whether or not *the calculating machine* has a mind is fundamentally the same problem as that of whether or not human beings (other than myself) have minds. Each one of us (allow me to assume the problem solved) is conscious only of his own mental processes, and assumes that his fellow beings have minds by analogy of their bodily behaviour with his own, which he knows to be correlated with mental processes.

Let us therefore solve the problem of the machine by constant reference to this older form of the problem, and by asking ourselves what it is in the actions of others that leads us to suppose that minds exist. Space is short, so it remains for me only to state my conclusion after comparing the behaviour of the machine with that of my fellow creatures. I am unwilling to postulate a machine mind, but I do think that this machine provides an excellent teleological argument for the existence of man.—*I am, etc.*,

Withyham, Sussex. P. DUPRÉ.

The Lock Hospital

SIR,—I have refrained from entering into any controversy concerning the fate of the above, with which I have been associated for forty-two years, but I feel that I must now do so before it is too late. The hospital is not being threatened because it is out of date, inefficient, or no longer required. It is a beautiful modern building, specially built for the purpose of treating venereal disease, and situated in the centre of London, where it is ideally placed for the purpose for which it was intended. It is the largest clinic in the West End, much larger than the clinics of any of the general or special hospitals. Patients come to it because they feel they will be treated with kindness, not as pariahs but as unfortunate, frightened human beings.

It was for their treatment that the subscribers to the hospital originally gave the money to build and equip it, long before the public conscience was roused to the necessity and importance of such treatment. They did not give these subscriptions to acquire honours or distinctions, but for the sake of the unfortunate mothers, innocent children, and foolish youths. They would deeply resent its transference to any other hospital, no matter how worthy of support, as long as the need for venereal treatment existed. An appeal is now being made to the Ministry of Health to stop this retrograde step before it is too late.

Everyone with any knowledge of these diseases, and the mental attitude of patients towards them, knows that Earle Moore, of Baltimore, was dead right when he said recently at the Royal Society of Medicine that one-tenth of the treatment was physical and nine-tenths psychological. I was a house surgeon when one injection of "606" was said to cure syphilis, and I have seen the consequences. I am hopeful we may not make the same mistake again through over-optimism.

I have been deeply touched by the anxiety shown by hundreds of old patients who have been coming specially to the hospital during the last two months, since the first rumours of the possible disaster to what they look upon as their hospital have appeared in the Press. Nobody seems to have thought of them in official circles.—I am, etc.,

London, W.1. J. JOHNSTON ABRAHAM.

Prevention of Sea-sickness

SIR,—With reference to your leading article on this subject (May 14, p. 855), it may be of interest to quote our impressions on the use of "dramamine." We have been reserving it for the cases in which hyoscine has been of little or no benefit. We have found that in almost every case dramamine has caused almost complete disappearance of the sea-sickness. As mentioned in your leading article, it seemed to us that the recommended dose was too high, and we find that 50 mg. twice daily will keep most people happy. We are now trying out 25 mg. doses.

It is, unfortunately, not possible in large, fast passenger ships to carry out controlled experiments, but meanwhile our impression is that dramamine is indeed all that it is claimed to be.—We are, etc.,

S. M. RUST.
R.M.S. Queen Elizabeth. F. W. A. FOSBERY.

Quality of Liver Extracts

SIR,—In recent months there has been some correspondence in the medical press in which it has been stated that the quality of British liver extracts made from "pharmaceutical livers" is inferior to those made from fresh, edible livers. Though none of the correspondence which I have seen gives any detailed evidence in support of the writers' views, it was nevertheless decided to inquire into the matter, as it is clearly one of considerable importance both for the welfare of patients at home and for the maintenance of the good reputation which British pharmaceutical houses have won in the export market.

In the course of discussions which have been held here no evidence could be discovered to substantiate the claim that better liver extracts could be made by using fresh, edible livers than by using so-called "pharmaceutical livers." The following points are worth noting.

"Pharmaceutical livers" is a trade term to cover livers which are tough or not sufficiently fresh in appearance to attract the housewife. It does not include tuberculous livers or those with abscesses, cysts, or other obvious disease, and such livers are not used for the manufacture of liver extract. There appears to be no risk of disease being transmitted to patients through the use of pharmaceutical livers, and in any case the production processes provide effective sterilization.

The vitamin B_{12} content of pharmaceutical livers and edible livers has been measured and no significant difference was found. B_{12} is not necessarily the only factor therapeutically active in liver, but at least this test appears to give a fair measure of the anti-anaemic activity.

It is true that rather wider variations in batches of liver extract are found than is the case with most biologicals, but this is due to the absence of an adequate animal test for standardization. The practice of the British pharmaceutical houses is to standardize their batches of liver by the response of one or two pernicious anaemia cases who have not had prior treatment. As the response of individual patients must vary widely, it will be seen that the standardization is less accurate than would be the case with a test using larger numbers and a "standard" strain of laboratory animals. This limitation, of course, applies equally to liver extracts manufactured in other countries. It does explain, however, how patients may occasionally not give the response which was expected. In such instances an alteration of dosage or change to another preparation will in most cases solve the difficulty.

The recent discoveries of folic acid and of vitamin B_{12} illustrate how little we yet know about the relationship of the liver to the macrocytic anaemias, and my Department would therefore be grateful for any scientific evidence on this matter which would assist in securing even better preparations for the treatment of patients suffering from these conditions.—I am, etc.,

Ministry of Health, London, S.W.1. W. DALRYMPLE-CHAMPNEYS.

Medical Fitness for Air Travel

SIR,—Dr. R. Lane (June 11, p. 1053) rightly refers to the great advantage of air travel to many invalids wishing to return to the United Kingdom for special treatment, and points out that he has sent home from Calcutta a number of patients who would have been excluded had the criteria given in our article (April 9, p. 603) been rigidly followed.

These criteria were given merely as a general guide to medical men for the safety and comfort of their patients on long flights, which are more arduous than Dr. Lane suggests, as even many robust individuals complain of fatigue after a flight from such a distance as Calcutta, and more so on longer journeys like those from Australia, the Far East, South Africa, and South America. Among the factors leading to this fatigue are the early hour of starting and the long hours (8 to 12 daily) of travel in a somewhat confined space at an average altitude of 8,000 to 10,000 feet, which is accompanied by a low but perceptible degree of anoxia. It is for the medical practitioner concerned to decide on the fitness of the patient for the proposed air journey on the general advice given, aided by his own personal experience of air travel and his knowledge of the patient.

The British Airlines' policy is to accept at the passenger's own risk all invalids who are vouched for by a medical practitioner as fit to undertake a particular journey, provided that the invalid's condition is not objectionable to other passengers. It is not true to say that in the case of any ordinary severe illness, provided a few common-sense precautions are taken, the risk to the patient is no greater than in an ordinary hospital bed: the anoxia and lowered atmospheric pressure exert a definite and deleterious effect on certain medical conditions, as outlined in our article. In one type of pressurized aircraft travel can be guaranteed at an altitude no greater than 5,000 feet.

It would be impracticable with the present number of passenger seats available in aircraft to have some of them reserved solely for invalids up to 10 days before the actual flight, but the Corporations' station managers are always willing to consider sympathetically the passage of invalids, including last-moment cases, and the practice is to place them in seats near the lavatory and where their attendants can be alongside them.

At present oxygen is always available for passengers in case of emergency, but when the use of pressurized aircraft becomes general the provision of an adequate oxygen supply will not be so easy, as the seating is arranged on as high a density as possible and the weight factor of several hours' supply of oxygen for each patient would have to be considered. It would not, therefore, be practicable to carry more than one or two patients who might need oxygen during the journey, as oxygen is not laid on in pressurized cabins, and special mobile oxygen apparatus would have to be provided.

Our recommendations were based mainly on Service experience and the known facts concerning anoxia and lowered pressure effects over various lengths of time at different altitudes, and which vary with the individual, depending on his physical condition and psychological make-up. The mortality rates for different diseases per flight cannot be stated, as we are not aware of the nature of every case carried in civil aircraft and as a large number of invalids travel without revealing that they have any disability. Fortunately, however, the annual mortality rate for all invalids carried is very low, owing, no doubt, to the care with which such cases are usually selected for air travel. It is wise to err on the safe side in transporting invalids by air, as it is very disconcerting, inconvenient, and expensive for them to be off-loaded *en route* should they be taken ill.—We are, etc.,

H. E. WHITTINGHAM.
A. BUCHANAN BARBOUR.
J. C. MACGOWN.

London, W.1.

Herpes Zoster Treated with Liver Extract

SIR,—I was very interested in Dr. H. S. Gaskell's article (June 11, p. 1037) on the treatment of herpes zoster by liver extract. It is a treatment I have consistently followed since 1946, when you published a letter from Dr. Hugh Dickie (June 15, 1946, p. 942), who advocated this treatment. The rationale is not very obvious, but I suppose it acts as a general "tonic."

In my list of cases, numbering twelve, there was only one in which there was not a rapid improvement and a very much quicker recovery than is usual in this painful complaint. The one exception was the case of an old lady of 82 who had other troubles, of which she died two years later.

The preparation I employ is "anahaemin," and one injection of 2 ml. is sufficient. The relief is rapid and noticed in 3–7 days.—I am, etc.,

Brighton. JAMES ROOTH.

SIR,—I have read with interest the article by Dr. H. S. Gaskell on the treatment of herpes zoster with liver extract (June 11, p. 1037). In *Paris Médical* (Aug. 14, 1948, p. 370) I gave the results of a few cases treated by 0.5 g. of liver extract; I hope presently to be able to give the results in more than 25 other cases. I can already say that though my results are good they are not as good as those of Dickie (June 15, 1946, p. 942) and Gaskell. This might be due to the different liver extract I have used.—I am, etc.,

Paris. M. MANSOUR.

Treatment of Basal-cell Carcinoma

SIR,—In reply to Dr. P. A. M. Robertson's letter (June 4, p. 1002) on recurrent rodent ulcers, his experience is all too common. If the recurrence occurs in or adjacent to a previous lesion I think it fair to assume that treatment was inadequate. If the fresh rodent ulcer is in an entirely new site it should be looked upon as unconnected.

Multiple basal-cell epitheliomata are not uncommon. I have recently seen a patient with eleven scattered over various parts of the body, which have been in existence for twenty years, gradually enlarging. They are sometimes quite superficial and occasionally respond even to repeated applications of thorium-X varnish. The fact of multiplicity gives support to the view that these lesions spring up from incompletely differentiated embryonal cells—i.e., they are not carcinomas, not derived from basal cells, but are naevoid tumours.—I am, etc.,

Brighton. I. P. MYERS.

SIR,—The reasons put forward by Sir Cecil Wakeley and Mr. Peter Childs (April 30, p. 737) in favour of exclusively surgical treatment of basal-cell carcinoma of the skin are hardly convincing. True, surgical excision may be regarded as a good second choice in some cases where an exceptionally skilled surgeon is available, but generally the results are inferior to those of radiation treatment. This has been my experience in a series of over 70 cases. Unless the excision is very wide relapses will occur: for basal-cell carcinomas have a tendency to form advance guards of strands of malignant cells far beyond the limits of the visible lesion.

The authors do not sufficiently emphasize the disadvantages of surgical treatment: unsightly scars; the consequential need of a second, plastic operation; the possibility of keloid formation; stimulation of the growth; and the very real danger of wound infection. None of these may occur if, as said above, exceptionally good surgical workmanship may be counted upon, but potentially they are to be expected after every operation.

Radiation therapy, on the other hand, has been so successful in the treatment of these tumours that a reversal to surgical methods must be regarded as a retrograde step. After all, gamma rays (produced by radium or the *x*-ray machine) have been proved to have a selective effect on the nuclei of tumour cells: their application is a biological procedure—which surgical excision is most certainly not.

In expert hands radiation of basal-cell carcinoma is a safe, clean, painless, and effective method, and in the large majority of cases preferable to surgery. (The late Dr. Sequeira, whose experience in this field was probably unique and with whom I had occasion to discuss the question of radiation or excision, was strongly in favour of radiation whenever possible and feasible.)—I am, etc.,

Nairobi. FRANK PIERS.

Oestrogenic Effect of Amphetamine

SIR,—The following may be of interest concerning the oestrogenic effect of amphetamine. Eighteen months ago I was treating a patient whose condition was rapidly deteriorating whilst on stilboestrol treatment for prostatic carcinoma. He was mentally depressed and had suicidal tendencies. Following administration of amphetamine (10 mg. daily), not only his mental but his physical condition improved markedly, and he appears to be in considerably better health.—I am, etc.,

Prestatyn, Flints. T. H. HARGREAVES.

Treatment of Stress Incontinence

SIR,—Mr. Wilfred Shaw (June 18, p. 1070) is to be congratulated for his ingenuity and for his courage in carrying out the pioneer work which together have produced another valuable contribution to vaginal surgery. There is definitely a need for an operation which can be employed where the modified anterior colporrhaphies have failed. It is essential that the operation performed shall not endanger the integrity of the bladder or the urethra, and it is also essential that it shall cure the condition.

Shaw's operations would seem to fulfil these requirements (I use the plural, for it appears that his technique is still undergoing modifications). The disadvantages at first sight are the formidable nature of the undertaking, the drilling of bone, which surgeons (orthopaedists excepted) naturally abhor, and the scar down the thigh. Curiously enough, the patients do not mind the last, and since the vaginal and vulvar incisions are lost sight of the operation, however formidable it sounds in print, leaves the patient with surprisingly little to show for it. We can accept that in 50 cases no instance of osteomyelitis has occurred.

After witnessing the operation, I have myself performed this on seven occasions and have encountered some teething troubles. Six of my patients are cured—the failure was a patient in whom the sling was brought up through the obturator foramina. It is a pity that this will not always do the trick, for it is easier and less formidable (and sometimes succeeds).

Mr. Shaw states that on incising the pubococcygeus "troublesome bleeding rarely occurs." It can do, however, but it is in my experience easily controlled by packing with ½-in. (1.3-cm.) ribbon gauze until the time has come to thread the strap through. I still use the arched incision including the clitoris; I have not found the bleeding here a nuisance, and have not had to drain. One patient has a sinus at the apex of this wound, presumably because I used silk sutures which have not yet separated.

One important point to keep in mind is that the operation will not cure cystocele. In the excitement of carrying through the Shaw operation step by step one can forget this. If the

patient has both conditions, then presumably after taking the strap from the thigh a routine colporrhaphy must be done and the strap threaded through before finally closing the skin.—I am, etc.,

London, S.E.3. KEITH VARTAN.

Toxic Effects of Antistin

SIR,—I was interested in Dr. Maurice Tobias's account of a case of poisoning by "anthisan" (June 18, p. 1098). I should like to record another case of overdose of an antihistamine substance, which did not, however, result in death.

The patient was a man, aged 46, who took about 20 tablets of "antistin" (2-N-phenyl-N-benzyl aminomethylimidazoline), while intoxicated, at 2 a.m. According to his wife, he lost consciousness within a few minutes of taking the drug, and his face became a dark red colour. He vomited profusely, and when seen by his doctor the following morning he was semi-comatose. He was sent to hospital, and on arrival was unable to answer questions, relapsing into stupor when left undisturbed. No abnormality was found in his tendon jerks. Plantar responses were flexor. Pupils were constricted. A well-marked "triple response" was obtained on scratching his skin. After gastric lavage his condition improved a little, but he remained drowsy for two days in spite of small doses of amphetamine. On the third day he was much better, and was fit for discharge on the fourth day.

It would appear that the toxic effects of antistin are entirely cerebral and resemble those of "benadryl," but that a larger dose is required to produce them (2 g.) with the former than with the latter drug.—I am, etc.,

London, S.W.1. HUMPHREY HAHN.

Zoster and Varicella in the Same Patient

SIR,—I was interested to read Dr. A. Courts's account (June 11, p. 1052) of the co-existence of herpes zoster with chicken-pox. I believe these cases are very rare.

In 1933 I attended a man aged 55 who had severe shingles of the third division of the fifth cranial nerve on the left side. His wife had had a mild shingles of the angle of the mouth a short time before. His was a severe attack with a temperature of 101° F. (38.3° C.). Three days later, after his temperature had fallen, it rose again to 102° F. (38.9° C.); he was acutely ill and developed a typical varicella rash. Recovery was complete in three weeks.—I am, etc.,

Purley, Surrey. C. E. TAYLOR.

Treatment of Cardiospasm

SIR,—Innumerable different operative procedures have been devised to treat cardiospasm. Some have produced no benefit, some have been completely successful, and some have created a worse condition which has ended fatally.

The aetiology of cardiospasm remains unknown. No satisfactory operation has yet been performed on the nerve mechanism controlling the cardia to overcome the spasm. The most successful results of treatment have been obtained by disrupting the circular muscle fibres which are in spasm. This may be carried out by dilatation with the Negus hydrostatic bag, or at operation by dividing the muscle fibres. When operation has become necessary, there are a few most important facts to which I should like to draw attention.

In a normal person the gastric contents are prevented from regurgitating into the oesophagus by two main mechanisms: (1) the action of the cardiac sphincter; and (2) the pinchcock action of the diaphragm. Any operative procedure which is embarked upon to cure cardiospasm must necessarily interfere with the first of these, but it is of the greatest importance to preserve the second—i.e., the pinchcock action of the diaphragm.

If both of these mechanisms are damaged by surgery a patulous cardia results. This produces oesophagitis and eventually peptic ulceration of the oesophagus, which is a worse condition and more difficult to deal with surgically than cardiospasm. The operation of oesophago-gastrostomy should only be mentioned in the treatment of cardiospasm to be condemned. It certainly relieves the obstruction at the cardia, but it creates a dangerous and killing anomaly, for there is nothing to prevent gastric juices regurgitating into the oesophagus. I know of at least one fatality from haemorrhage following this operation, which came from peptic digestion of the oesophageal wall.

In Leeds, a modified Heller's operation has been performed on those cases which did not respond to dilatation with the Negus hydrostatic bag. This is a safe operation, for it does not interfere with the pinchcock action, and post-operatively there has been no regurgitation into the oesophagus. It has given excellent results both symptomatically and radiologically the seventeen times it has been performed. It is the operation of choice, because other operative procedures, altering the cardiac mechanism, may prove to be dangerous.—I am, etc.,

Leeds. G. H. WOOLER.

Treatment by H 11

SIR,—I enclose leaflets on H 11 which I received by the penny post. You will note there is nothing to show who is the sender of these leaflets. I would like to protest strongly against this method of advertisement of a treatment for such an important disease as cancer.

In 1943 H 11 was tried out in a case of bronchial carcinoma. The patient was in a large chest hospital. All facilities were offered to the Hosa Laboratories for the investigation and treatment of the case personally, but these were refused. H 11 was tried out by the medical staff of the hospital, but the treatment failed and the patient died.

I make my protest as I feel that it is most undesirable that hopes should be raised of a cure of cancer.—I am, etc.,

Dorking. P. H. PHIPPS.

Treatment of Thyrotoxicosis

SIR,—The issue of the *British Medical Journal* of April 16, 1949, has only recently come to hand in this part of the world, and the remarks made by Sir Heneage Ogilvie (p. 645) regarding thyrotoxicosis in his otherwise excellent address, "In Praise of Idleness," are by no means in accord with one's experience here nor with that reported from Canada and the U.S.A. The intelligent use of thiouracil and its derivatives in acute thyrotoxicosis has completely revolutionized the treatment of this condition and is paralleled only by the introduction of the antibiotics in other spheres of general medicine.

I have published several articles in the *Medical Journal of Australia* principally on the use of methyl thiouracil in long-term therapy in the acute primary type of toxic goitre, and in a series of 120 cases treated with thiourea and thiouracil and another series of 200 cases treated with methyl thiouracil the results show complete control of the thyrotoxicosis with restoration to normal health and recession of the gland in 80% of cases. In a further 10% there was control of thyrotoxicosis, but an enlarged gland persisted. Recurrences were under 5% and always occurred in the latter class, so now all such cases are subjected to operation. The other 10% for various reasons were operated upon, several because of some sensitivity to the drug, others because they would not or could not carry on with prolonged treatment, and others again for cosmetic reasons.

All the cases have been followed for a minimum period of six months after concluding treatment, and many for two to five years, without recurrence. In addition all secondary cases of thyrotoxicosis associated with old colloid or adenomatous goitres are subjected to short-term therapy until the toxic condition is under control, and then operation is carried out. In this class I now have close on 500 cases.

The figures quoted by Sir Heneage Ogilvie are deplorable, and if they are the average of English experience then it is high time the methods of therapy in vogue should be reviewed and altered drastically. In the 800–900 cases personally treated or under treatment since the "thio" compounds were introduced in 1943 I have had two cases of agranulocytosis—one in the early days and one where a patient developed an acute pyelitis and was given large doses of one of the sulphonamides by her local doctor. Slight reactions have been noted in only 3% of cases, and in only 0.5% of cases was treatment stopped because of a febrile reaction or a leucopenia. The mortality rate has been *nil* for the whole series. Seventeen patients have

been treated during pregnancy and delivered safely with normal babies. Quite an appreciable number of woman have had one to three children after concluding long-term therapy without any recrudescence of the thyrotoxicosis, and I regard this as a good test of "cure."

The mortality rate of surgery in expert hands with the iodine regime was 0.25–1%, but the overall general surgical mortality is nearer 5%; and, even so, many cases are only just pulled through after several very anxious days, whereas with the thiouracil preparation there is seldom any post-operative reaction that would worry either the nursing staff or the surgeon. So far my operation mortality rate is nil, and similar large or larger series are reported from the U.S.A.

It seems that the "week's reflection in the relative anoxia of 12,000 ft.," to which Sir Heneage refers, has made him unduly dogmatic in his pronouncements regarding thiouracil, and he has not exercised that personal supervision of his cases and that clarity of thought that one expects from him. He states he has "not drained a thyroid for 10 years"—possibly a safe proceeding in his capable hands, but not wise advice to give the average young surgeon, as a split tube or corrugated rubber drain for 36 hours is safe in certain cases and leaves no reminder.

As regards the "considerably enhanced difficulty" of operation, I find in cases properly prepared there is no greater difficulty with the large hyperplastic glands prepared with thiouracil and iodine than there is with those prepared with iodine alone, while with the adenomatous glands, even in those patients who have been fibrillating, one is freed from worry and strain both during and after operation, as also is the nursing staff. Perhaps the difference in our results is that I personally supervise both the medical and surgical treatment of all my cases, and it is I who decide if and when the patient should be operated on.—I am, etc.,

Sydney. H. R. G. POATE.

Nutritional Macrocytic Anaemia

SIR,—For the record, Drs. J. Rubie and C. D. Calnan (June 18, p. 1079) may like to see the report of a case of megalocytic anaemia in a young vegetarian (April 22, 1944, p. 558). This young man had a severe "pure" anaemia (without skin or mental changes) which responded promptly to "anahaemin." An initial histamine-fast achlorhydria gave place to a spontaneous secretion of free acid 17 months later; and a presumptive diagnosis of pernicious anaemia was finally ruled out of court.—I am, etc.,

Hartlepool, Durham. R. T. COOKE.

Marriage Guidance by Doctors

SIR,—I would refer to the recommendations of the Royal Commission on Population regarding instruction and advice to the public upon sexual life and behaviour, now at last recognized as of paramount importance to the welfare of the nation. While recognizing the overcrowded nature of the syllabus confronting the medical student, I would wish to propose that in the interests of all concerned some room should be made for the training of the aspirant-doctor in the understanding not only of sexual physiology but also of sexual psychology, including the psychological differences between man and woman, the stresses of women's problems, and the use of birth control, not for avoidance of parenthood but for the proper spacing of families.

It is a regrettable fact that at the present time many otherwise excellent G.P.s have a repugnance to giving advice upon sexual problems, even while they can hardly not be aware of the tremendous incidence of troubles of this nature among their patients and their results upon physical and psychological health. Most of these men have acquired a good deal of insight during their years of practice; but there are many who are unable, through not knowing quite how best to approach it, to give impersonal and yet humane advice in such cases.

Since the subject's importance—indeed, its fundamental character—is now for the first time officially noticed, and since it appears that such help and advice may come within the scope of the health services of the State, it would seem that the need for training of young doctors in this direction is both vital and urgent. If doctors, busy and, indeed, overworked as they all are, can rise to meet this opportunity, I feel that they will be well rewarded. A sympathetic understanding of these human problems will go far to strengthen the ties of good will between doctor and patient, confirming ever more strongly the position of the "family doctor" as an essential and honoured part of our social life.—I am, etc.,

London, W.1. EUSTACE CHESSER.

Adoption Bill, 1949

SIR,—Miss Anne Ashley's admirable letter (April 23, p. 725) embodies all the principles the National Council for the Unmarried Mother and her Child works for. Above all, we warmly endorse her insistence on the right and privilege of the mother to take a decision about her child's future "with proper safeguards and never in a hurry." It is for this reason that this council presses for an amendment of paragraph 3, subsection (2), of the Adoption Bill, 1949, which would, as it stands, allow a consent to be given "whether or not an application for such an order is pending." This section provides for a mother to abdicate from her position and to sign away her child directly after birth, thereby possibly depriving her of the responsibility of taking this decision at a later time.

It is these insufficiently considered and hastily arranged adoptions which bring trouble only too often to the mother and to the adopters alike: much careful thought over a period of many years has served to emphasize the importance of the time factor. Experience has shown that doctors not infrequently encourage adoption at this early date, even when the mother herself wants to keep the child. This council urges the medical profession to use its influence to secure the amendment of this clause when the Bill comes before the House of Lords, and above all asks doctors to consider each case on its merits before recommending adoption.—I am, etc.,

LETTICE FISHER.
London, W.C.1. Chairman, National Council for the Unmarried Mother and her Child.

POINTS FROM LETTERS

Zoster and Varicella

Dr. A. F. DUNN CARRIE (Manchester, 15) writes: Some years ago I attended a female child aged 2 years for a typical attack of chickenpox of moderate severity which ran a normal course till the tenth day, when she developed a well-marked herpetic eruption along the distribution of the fifth dorsal nerve on the left side. As is usual in young subjects, the herpes was attended with little discomfort or pain and subsided spontaneously, requiring no treatment other than the application of a dusting powder.

Milk and Rheumatic Fever

Dr. JOHN T. MACLACHLAN (Glasgow) writes: Two years ago I expressed the opinion in the *Journal* (May 31, 1947, p. 784) that rheumatic fever was probably due to milk from infected rheumatic cows. In my opinion this induction will be clinched if pasteurization of milk destroys the infection of rheumatic fever. Some doctors tell me that rheumatic fever seems to be rare. It would be worthwhile making rheumatic fever a reportable disease to determine this very important point.

Horseflies and Poliomyelitis

Dr. RICHARD V. WRIGHT (Coldbeck, Cumberland) writes: During the summer of 1947 I noticed that the blood-sucking horsefly was very prevalent and a nuisance. Recently, swimming in Lake Loweswater, I noticed these blood-sucker flies made the habit of pouncing upon other flies, including the *Musca domestica*, bringing them pick-a-back to ground and then sucking their abdomens. Now the musca has been shown for certain to carry the virus of poliomyelitis in its intestine, and thus the horsefly could be easily infected on its perforating proboscis, and then infect the next mammal it attacks, and so be the vector into the blood of humans. And this would also account for horses being so commonly affected by poliomyelitis during an epidemic, and also for bathers being attacked so readily by the infection.

Medical Notes in Parliament

THE NATIONAL HEALTH SERVICE (AMENDMENT) BILL

A Standing Committee of the House of Commons began on June 28 the examination of the National Health Service (Amendment) Bill (see *Supplement*, May 21, p. 274). On Clause 1, which is concerned with existing partnership agreements and modification of those agreements, Mr. BEVAN moved and the Committee accepted an amendment for the purpose of making clear that the free transfer of one share in a partnership to another person was in fact affected. The words substituted were "in lieu of the payment of the purchase price by the partner to whom the share is transferred."

Mr. WALTER ELLIOT pointed out that there was a difference of opinion between the Government and the Opposition about the number of persons affected by the Bill. The Financial Memorandum accompanying the Bill had estimated that about 50 practices were involved and that the number of doctors concerned was nearly 150. The Lord Advocate had said on the second reading that only one of these was in Scotland. It was the view of the Opposition that a much larger number of persons was affected. The mere stipulation to bring in a new appointed day showed that the controversy which the Bill was designed to clear up affected a very large number of practitioners, possibly half the number in the country who were in partnerships and a very large number of assistants. The Bill dealt with a problem which affected the whole profession and to which the whole profession had taken grave exception.

Sir HUGH LUCAS-TOOTH said that the clause applied to all partnerships in existence on the appointed day. In Subsection (3) it provided that Section 35 of the National Health Service Act which prohibited the sale of medical practices should be deemed never to have affected the exercise under any partnership agreement of any right or obligation of a partner to sell to, or purchase from, another partner any share in the goodwill of the practice. He thought that in the Bill they were arriving at a happy solution of the problem. On the other hand the Government should be asked whether it had any information about the dissolution of partnerships. In was possible that some practitioners had decided that it would be better to dissolve their partnerships before the original appointed day and to recast them in the light of the known defect of the principal Act. If that were so, certain hardships might not be covered by the clauses of the Bill.

Mr. BEVAN replied that how many cases were affected was purely speculative. He agreed that apprehension of the effect of these clauses had been created among a large number of doctors by irresponsible propaganda in 1946 and 1947. The Ministry had no information how many partnerships, if any, had been dissolved as a consequence. Mr. Bevan explained that in speaking of irresponsible propaganda he referred to sensational headlines which gave rise to fears among a large number of general practitioners. The House, however, knew from experience that larger numbers of doctors had joined the Service than had at the time been estimated to be necessary. The number of partnerships affected by this propaganda would be demonstrated by the number of persons coming forward for compensation. He thought they would be very few.

On Clause 3 (right of medical partners to be entered on lists after appointed day) Sir HUGH LUCAS-TOOTH said the period of two months from the date of the passing of the Bill was reasonable, but there would be exceptional cases in which compliance would be difficult. Doctors who had gone overseas or were ill might require a longer period. It would probably have to be at the discretion of the Minister or some outside body.

Mr. BEVAN hoped he would not be pressed on this. It was impossible for the British Medical Association to arrange for the distribution of the compensation fund while the matter was in doubt. The Bill could not be placed on the Statute Book before the end of July, and the Long Recess would follow, so the profession would have ample notice.

On Clause 5 (modification of other medical partnerships in force on the appointed day) Mr. BEVAN moved an amendment having the effect of giving to all members of a partnership to which the provisions of the clause applied the benefits of Subsection (2). He said that as the subsection was worded the obligation of a partner outside the Service to purchase, in pursuance of an agreement in force before the appointed day, the share of a partner who joined the Service after the appointed day was converted into an option, whereas the obligation of a partner who was inside the Service to make a similar purchase had not been so converted. His amendment with the subsequent one would bring the clause into line with other provisions in the Bill which turned an obligation into an option in cases where the purchaser was acquiring something less than he had contracted for and something which, owing to the provisions of the original Act, he could not sell.

Mr. ELLIOT said this could reasonably be regarded as an easement. On the understanding that the Minister had disclosed the whole meaning of the amendment the Opposition consented to its incorporation in the clause. The amendment and the further consequential one were then accepted and the clause as amended was ordered to stand part of the Bill.

On Clause 6 (existing agreements with medical assistants) Mr. ELLIOT said these had scarcely been mentioned in the debate on the second reading. He believed that the number of assistants affected would certainly reach 1,000, and might be 1,300 or more. He took it that all these were covered by the clause. If it were thought that the clause merely applied to the 50 practices which had been referred to, dismay would be created among those whom the Bill was intended to benefit.

The LORD ADVOCATE (Mr. John Wheatley) said that following the recommendations of the Slade Committee the Government proposed to apply the same principles in this Bill to assistants as were applied to partners within a partnership agreement covered by the Bill. He gave an assurance that assistants were included within the clause in the same manner as partners within a partnership agreement. The number of assistants affected was a matter of speculation. Information on that point should have been more readily procurable from the medical profession and medical organizations than from the Government.

Mr. ELLIOT hoped that if at any subsequent stage of the Bill the Opposition brought forward information derived from the professional organization, its submissions would be received in a spirit of sweet reasonableness. The clause was then ordered to stand part of the Bill.

On Clause 7 (removal of hardships) Sir HUGH LUCAS-TOOTH moved to provide that where the arbitrator or committee acting under the powers conferred by the clause modified the operation of the Act of 1946, or of this Act or of any regulations in relation to the provisions of the agreement, it should immediately report such modification to the Minister, who should from time to time lay a statement before Parliament giving brief particulars of all such reports. Sir Hugh said that the power to vary the Acts and the consequent regulations was wide but necessary. It behoved the Committee to see that what Parliament had laid down was effectually carried out. The subsection might enable a coach and horses to be driven through what Parliament had decided. Two or more doctors could conceivably appoint an arbitrator without the knowledge of the Minister or of Parliament and persuade that arbitrator to modify the provisions of the principal Act and of this Bill. The Committee agreed to the amendment.

Prohibition of a Salaried Service

On Clause 10 (prohibition of full-time salaried practitioner service) Sir HUGH LUCAS-TOOTH moved to insert an amendment providing that payment "except in special areas or except where a basic salary had been granted should consist of remuneration ascertained in relation" . . . to the number of patients. Sir Hugh said the words "special circumstances" were in no way defined in the clause, and the words "wholly or mainly" were without a clear meaning. On the second reading Mr. Bevan had been asked whether these words would enable him to provide by regulation for all doctors to be paid up to 49% of their remuneration by way of salary. As the Minister

in his reply had failed to answer that question Sir Hugh thought the Committee must assume this was a fair interpretation of the phrases which he had quoted. They should have a clear statement from Mr. Bevan on what he thought the words meant. The Opposition in the amendment which he had moved and in the following one wished to provide that the remuneration should consist of remuneration in relation to the number of patients, except in the case of special areas and the case in which a basic salary had been granted. In its second amendment the Opposition proceeded to give definition to the terms "special areas" and "basic salary." It was desirable that the Committee should clearly indicate to those who were to be in the Service what the rights and obligations of those in the Service were likely to be. It was unsatisfactory that people should be expected to enter the Service not knowing how far the terms of service might be altered, because Parliament contemplated that a doctor having once entered the Service at the age of 25 would continue to serve until he was 60 or even 70. In the amendment basic salary was defined as being such salary as might be determined by regulations made under Subsection (1) of Section 33 of the Act of 1946 or the corresponding section of the Scottish Act, and the amendment provided that it should only be payable to a medical practitioner for the purpose of making special provision for meeting cases of hardship or otherwise to provide special assistance to particular classes of practitioners. In the section dealing with special areas power was given to the Minister to provide by regulation for any part of a doctor's remuneration up to 100% to be given by way of salary in special areas where entirely special circumstances prevailed. The obvious case was that of the Highlands and Islands. These amendments carried out the desire of members in all parts of the Committee within the meaning of the pledge which had been given.

Mr. BEVAN said he had made it clear again and again during the controversy which accompanied the launching of the National Health Service Act that it was not the intention of the Government to introduce a whole-time salaried service.

Sir HUGH LUCAS-TOOTH: "Not while the fruit is green."

Mr. BEVAN said that when he had talked about the fruit being green he had meant that the ethical standards of many people would have to be raised before they could be trusted to do their job without the application of rewards and punishments. Even in the Opposition amendment the cases to which it should apply were not defined narrowly. "Or otherwise" was as wide a phrase as that of the Bill itself. It was clear that the Minister should be able to pay a young man in the Service a salary of £300, which might amount to more than half his remuneration. It might also be the fact that aged practitioners who were quite useful might have a declining list which would make the basic salary more than half their remuneration. The Opposition did not contest that this might be desirable and necessary. It was also common ground that it might be necessary for salary to be paid in certain areas because the number of people living in that area would not suffice on a capitation basis to reward adequately the general practitioner. What was left was a suspicion that the words in the clause would permit some Government at some time to impose clandestinely on the medical profession a full-time salaried service before they were prepared to accept it. Never was there a more unworthy suspicion or a clumsier way of trying to meet it. Statutory power was not what the Minister required in such circumstances. What was wanted was the willingness of the profession to accept what was proposed, and no amount of statutory protection would deal with that position. Even if the language of the Opposition were put into the Bill a Minister would have exactly the same latitude as was given in the Bill. Sir Hugh had said he thought the language of the Bill gave effect to the pledge Mr. Bevan had offered in the House. Why then was it necessary to refine this language?

Mr. ELLIOT said the Minister was arguing that because the Opposition had made an attempt to meet him and to give latitude which they realized was necessary the case they had advanced could be brushed aside. Mr. Bevan had asked the Opposition to clear its mind of subjective consideration. Medicine was largely a matter of subjective consideration. Many of the chromium-plated figures of modern health administration were not so satisfactory to the patient as one who showed himself sympathetic and anxious to deal with the human problem of a sick man. In all these matters the Opposition was concerned to maintain the human contact between doctor and patient, which tended to be diminished when a vast central organization came into the matter. Mr. Bevan had referred to his efforts to raise the ethical standards of the medical profession.

Mr. BEVAN replied that when he had said that in many professions ethical standards were not yet sufficiently high to exempt them from State assistance and that they therefore could not be trusted with a full-time salary he had not referred to the medical profession.

Mr. ELLIOT said that if the Minister told the Committee that he had been indulging in a poem more suitable for an Eisteddfod than for a committee of the House of Commons the Opposition was willing to let the matter go at that. He suggested that the Minister should raise a flag when he came to one of his general metaphors but lower it when he came to a concrete application. The step-by-step technique in introducing changes was familiar, and the legal maxim of resisting the beginnings was sound. The form in which the Opposition would cast the clause was positive and indicated the line of approach they might take at subsequent stages.

Mr. BEVAN suggested that the language of the amendment was more dangerous than the language of the Bill, because it made it possible to give a decision on hardship and thus to take in classes of general practitioners.

Sir HUGH LUCAS-TOOTH said that if the Minister objected to the words "or otherwise" he was willing to take them out.

Mr. BEVAN said he had no objection to these words, but to the whole amendment.

Mr. ELLIOT said the Minister would not deny that the medical profession would like to have the amendment.

Mr. BEVAN said he had no evidence that the medical profession would like it. He strongly advised the medical profession not to support the amendment, because it was more capable of being misrepresented than was the language of the Bill.

Mr. ELLIOT assured Mr. Bevan that the medical profession considered the amendment a desirable step.

Mr. LINSTEAD said the Minister seemed to be taking powers in the clause as drafted which would enable him, if he thought there were special circumstances, to apply a fixed salary over the whole profession. If that was not the meaning of the Bill then the Opposition had cleared up a point which was in doubt. The suspicion that the profession would be faced with a full-time salaried service resided in the profession, and it was unjust of Mr. Bevan to pin it on to the Opposition. The dental profession was definitely afraid that an opportunity would be taken to introduce a full-time service paid by fixed salary. The value of the discussion that day had been on the one or two additional assurances the Minister had given of the present intentions of himself and his Government.

Basic Salary

Mr. BEVAN said the Opposition pretended it was speaking for the profession and the country. What it was really doing, and had done ever since 1946, was to stir up as much mischief as possible against the National Health Service Act. Sir Hugh Lucas-Tooth was attempting to induce in the mind of every doctor a suspicion of the Government's intention. Over the last two or three years the Opposition had done its best to sabotage the whole of the health service administration. It was time the country knew this. The Committee had before it an innocent clause carrying out the pledge which he (Mr. Bevan) had given to the medical profession. Every doctor understood it clearly. He had received no letters about the clause and did not believe there was any doctor who did not trust the intentions lying behind the clause. Why should he give Sir Hugh a pledge? He was not entitled to it. What was happening had been agreed between the Government and the medical profession. The profession might wish to alter the arrangements, as there was a great deal of doubt in the minds of doctors about the basic salary. With the ordinary administrative machinery at its disposal the medical profession could make the basic salary practically universal. Many doctors

had bitterly complained that the profession itself was withholding the basic salary which they thought they ought to have. What the Ministry had said was that it must satisfy itself that it was dealing with a bona-fide general practitioner. If a person merely put up his plate and said, "I am a general practitioner" and made a claim, then, said Mr. Bevan, he would not pay £300. There had been instances where he had refused to pay £300 because on inquiry he was satisfied that the applicants were not seriously practising their profession. It might easily happen at any time that the profession might come to him and say they would like to have the basic salary universal to all genuine medical practitioners. Until they did so he would not make it universal. That was the only pledge he was prepared to give. He was not prepared to put the whole of the conditions for the payment of the medical profession within a statute so that the Ministry could not move without altering that statute. Beyond the three categories of doctors for whom the basic salary was necessary—the young doctor who wanted to avoid borrowing money at exorbitant rates of interest, the old general practitioner who wanted to continue practising, and doctors in places where the population was too sparse to give reasonable remuneration—it was not in the mind of the Government to introduce a universal salaried service.

Mr. ELLIOT said Mr. Bevan was arguing along two opposed lines. He was saying that he did not wish to alter the conditions and also that he did not like the amendment because it might interfere with him if he desired to alter them. Mr. Bevan's idea was that the whole of the difficulty between himself and the medical profession arose from the arguments introduced by Conservative M.P.s. He should have noticed in the course of his political life that he was capable of stirring up opposition without the support of Conservatives.

Mr. BEVAN: And of dealing with it.

Mr. ELLIOT said Mr. Bevan must not object when the medical profession felt that he should be treated with a good deal of circumspection. The Minister could point to no instance where the Opposition had attempted to sabotage the working of the Act. He assured Mr. Bevan that the Opposition had the upport of the doctors on this amendment. Later, on the ques ion of arbitration, the Opposition could refer to the proceedings at the conference of the B.M.A. in Harrogate.

Mr. BEVAN said his recollection was that the Harrogate conference had never raised the question of the basic salaries. The Government had received no communication from the doctors about the clause.

Mr. ELLIOT said he could give an assurance that these matters had been discussed with the representatives of the British Medical Association.

Mr. BEVAN asked whether he was to understand that the Opposition had been in communication with the British Medical Association about the amendment though the Association had made no official representation to the Government.

Mr. ELLIOT recalled that earlier the Minister had said that any such approach had his entire approval and that he would accept it from the Opposition. Naturally the Opposition, as responsible persons, did their best to discuss such matters with other responsible people.

An "Intrigue" with the Opposition

Mr. BEVAN said this was astonishing. They had got o the point where the British Medical Association's repre- entatives carried on an intrigue with the Opposition. Had hey got to backstairs intrigues between the Opposition and he medical profession about a Bill before the House of Commons implemented a public pledge given to the House by the Minister of Health? The duty of the British Medical Association, if it thought that the Bill did not give effect to the pledge, vas to come to the Minister of Health and say they did not like he words. They had not come.

Mr. ELLIOT said the Opposition had brought forward the mendment entirely on its responsibility as Members of Parliament. The amendment had been advanced after taking counsel, ut it was advanced solely on the responsibility and on behalf f the Opposition—not of the British Medical Association. The)pposition had never claimed that it spoke with the support of the whole medical profession. He did say that the medical profession was profoundly suspicious of the Minister. The accusation made by the Minister that the amendment was part of a deliberate attempt to sabotage the health service was not justified by the words and arguments which had been used.

Backstairs Pressure

Mr. BEVAN said the British Medical Association had met his officials on this Bill, but on no occasion had they raised the question of this clause. It was the duty of the Association to raise such issues with the Ministry if they wished to call attention to what they considered to be the inadequacy of the language in the Bill. It was exceedingly difficult for the Government to carry on discussions with responsible organizations if those organizations did not use the channels of communication open to them and used backstairs ways of bringing pressure to bear on Members of the House.

Mr. ECCLES said the point of the Bill, of the clause, and of the amendment was to make the Service work better. The Opposition intended that the amendment would help to make more doctors willing members of the health service. There was no question of the amendment having been put down to exacerbate the doctors in the Service, who were still highly suspicious of the Minister.

Mr. BEVAN said that was the characteristic attitude of the medical profession towards every Minister in every country of the world. It was the Opposition which had introduced personalities about the Minister. That was not true about members of the medical profession, but had been deliberately created by the language of the Opposition.

On a division the proposed amendment was then rejected by 13 to 7.

On the motion that the clause stand part of the Bill Sir HUGH LUCAS-TOOTH said the Opposition had not been approached by the British Medical Association or by any official person in the Association about an amendment to the clause. He and his friends had drafted the amendments. They were subsequently seen by the British Medical Association, which took no initiative in the matter, though those members of the Association who had seen the amendments whole-heartedly approved them.

Mr. BEVAN said Sir Hugh's statement must be taken with a large slab of salt, as it contradicted what had been said earlier. He hoped Mr. Elliot would give the Committee some clarification of a serious accusation. It had been said that Opposition members had been in touch with leaders in the medical profession. The Committee should have a frank disclosure of the names of those consulted and their relations with the Conservative party and the British Medical Association.

The Chairman (Sir Charles MacAndrew) said that the debate on the motion that the clause stand part of the Bill was very narrow, and he could not allow those questions to be answered.

Mr. ELLIOT said the Opposition had made a statement on how the amendment was drawn up. It had been shown to responsible persons. It would be wrong for him to go beyond that.

Mr. BEVAN said the Opposition would much regret that morning's work.

Mr. ELLIOT said the Bill imperfectly carried out a pledge given by the Minister in response to representations made by the Opposition after consultation with responsible persons. The Opposition was prepared to leave the matter there.

The clause was then approved, as also was Clause 11.

Settlement of Disputes

On Clause 12 (reference of disputes as to conditions of service of persons employed in health services), Mr. LINSTEAD, on the motion that the clause stand part of the Bill, said it would be helpful to have an elucidation by the Minister of a number of points. Under the clause, disputes over conditions of service or remuneration could be dealt with by conciliation or

Menopausal Syndrome

'Estigyn' provides an effective means of treatment of menopausal disorders resulting from a decline in the secretion of œstrogen by the ovary.

'Estigyn' is a highly potent œstrogen derived from natural sources and is active orally. In addition it is non-toxic.

The improvement in subjective symptoms and the restoration to normal outlook is, in many cases, gratifyingly rapid while at the same time the possible onset of pruritus vulvæ or kraurosis vulvæ is prevented.

FOR COOLNESS AND COMFORT IN WEAI

Lastonet

PRODUCTS

FEATHERWEIGHT ELASTIC STOCKING

This ideal made-to-measure surgical stocking *is available under the National Health Scheme.* In thigh or knee lengths, ensuring perfect fit with complete comfort. Made entirely of net, the stocking is cool to wear, allowing free circulation of air over the skin. Invisible under the normal stocking. Measurement forms obtainable from leading Chemists or in case of difficulty direct from the makers.

ELASTIC SUPPORTING BANDAGE

The perfect elastic net bandage for weak joints, sprains, etc., giving a firm support and being cool, compact, light and inconspicuous. Hygienic and easily washable. Available in 2½", 3", 3½" and 4" widths, from leading Chemists.

LASTONET PRODUCTS LTD. · CARN BREA · REDRUTH · CORNWALL

could go to the Industrial Court, or to arbitration by arbitrators appointed by the Minister of Labour, or to arbitration by a body appointed by agreement by both sides with a chairman appointed by the Minister of Labour. The crux of the procedure was that there could be no arbitration until both sides were agreed that there should be arbitration. If there was a dispute between the Minister and a section of those serving within the Service, the Minister apparently could refuse to allow that dispute to go to arbitration. Under Section 66 of the principal Act the Minister had power to make regulations prescribing the qualifications, remuneration, and conditions of service, so that if he refused to consent to arbitration he could use his power of making regulations and leave the dissatisfied parties with the sole alternative of approaching the Opposition so that a prayer against the regulations could be moved in the House. Mr. Linstead could not feel that the Minister intended the references to arbitration to be a one-sided gesture. He assumed the Minister intended that when there was a dispute he would not use his power to withhold consent and so prevent that dispute going to arbitration. If Mr. Bevan would say so he would go a long way towards clearing up the purpose of the clause. Mr. Linstead recalled that the Secretary of State for Scotland had given an undertaking to Scottish pharmacists that arbitration would be open to them under this clause. Mr. Linstead asked three questions of the Minister. Did he accept the principle of arbitration as the method of settling disputes which arose on remuneration? Did he regard arbitration as binding on the Crown? If a dispute went to arbitration, would the Minister regard himself as bound by that award, despite the suggestion that the award of an Industrial Court or of an arbitrator could not be binding on the Crown?

Mr. BEVAN asked for an assurance that these questions were not put on behalf of the medical profession.

Mr. LINSTEAD said he had not discussed the matter with any representatives or members of the medical profession and took personal responsibility for putting the inquiries.

Mr. BEVAN said he was glad to have that statement. What was under discussion was an agreement forming part of the participation of the medical profession in the Whitley machinery. The Conciliation Act, 1896, and the Industrial Courts Act, 1919, did not provide for compulsory arbitration, and the present Bill would be an inappropriate place in which to amend those Acts. It had always been held that it would be highly undesirable to have compulsory arbitration under those Acts. The whole purpose of the Whitley machinery was to bring about agreement without arbitration. In the course of the last year agreement had been reached over many matters, especially those concerning nurses and domestic workers in hospitals. It had been a wide range of agreement without resort to arbitration. He much regretted that in the last few months some members of the National Health Service had talked insistently of arbitration before negotiations had begun. That was as though there was an intention to disagree, and that arbitration was inevitable. There was every reason why the machinery of the industrial courts should not provide for compulsory arbitration, because arbitration, once it was made compulsory, meant that it was impossible to vary an award. If the award was imposed like a clamp, any mistake was immediately converted into fact and caused the most irritating conditions for both sides. Nothing new was being done in the clause. All the Government sought to do was to provide for ultimate machinery in the event of a breakdown. He could not agree beforehand that everything should go to arbitration. The Spens Committee was not arbitration. It might be much better to have an inquiry to lay down general principles, guiding any future agreement on a particular matter.

Arbitration

Mr. LINSTEAD asked whether the Minister felt he should refuse arbitration when the other party in a dispute desired it.

Mr. BEVAN said discussions were still going on about the nature of the agreement. When those discussions took place the question of arbitration would arise and would be written into whatever agreement might be reached. All the Bill did was to give powers to enable an agreement to be made. The Committee was not writing an agreement into the Bill. To insert an arbitration clause would not be proper, because the present clause covered every element in the National Health Service and it was necessary that the Ministry should have power from Parliament to enable the machinery to be established. He recalled the case of the Burnham machinery where, after discussions between both sides, a report was made to the Minister of Education, who might or might not implement it. If both sides agreed to go to arbitration, obviously the Minister of Health would accept the consequences of the arbitration. It was much better that in each particular case what should go to arbitration should be decided in regard to the circumstances and not beforehand. The fixing of fees was not a matter upon which the Ministry of Health could agree beforehand to go to arbitration. It was much more complicated. The Government could not, over the vast field of National Health expenditure, say beforehand that Parliament should put it out of its power to consider the fiscal consequences of an arbitration. That was why he did not agree beforehand to compulsory arbitration over the whole field. The Committee should not say beforehand that neither the Chancellor of the Exchequer, nor the Government, nor Parliament, but someone else should determine the operation of public revenue and public expenditure. The fact that regulations had to be made implied the right of the House of Commons to refuse these regulations. Mr. Bevan asked if they wanted to put this outside the power of the elected representatives of the people to decide and to have a Fascist set-up. Only in most exceptional circumstances would the House of Commons throw out a regulation reached after arbitration, yet it must have that residual right.

Sir Lionel Whitby's Letter

Mr. ELLIOT said Mr. Bevan had made a statement in convincing language about the necessity for leaving discretion to the Minister when dealing with claims which might result in demands on the public purse. But the contrary opinion seemed to have arisen in the minds of responsible persons in the medical profession. Since there had been arguments on the channels of information by which the Opposition could legitimately ascertain opinion outside the Committee, Mr. Elliot said the responsible person whom he cited was Sir Lionel Whitby, the retiring president of the British Medical Association. He quoted a letter by Sir Lionel appearing in *The Times* of June 20 which said that in proposals issued in October, 1947, the Government had stated that they were anxious to accord the fullest rights to arbitration, subject to preservation of the Government's prerogative. Sir Lionel had added that it seemed the Government had forgotten a pledge given to the medical profession before the start of the National Health Service. That letter had led to a resolution passed at Harrogate recording with regret that the Minister and Ministry had shown little or no desire for co-operation with the profession in its efforts to serve the public, that they had met the profession's suggestions with indifference and procrastination, and that they had been guilty of breach of faith. Mr. Elliot took it that Mr. Bevan felt his conscience was entirely clear in the matter. His argument, however, was not written on a clean sheet of paper. It came at the end of long negotiations in which it would be most unfortunate if any suggestion of breach of faith were not immediately dispelled.

Sir HUGH LUCAS-TOOTH said that, whereas a doctor employed on his own account could go to arbitration and demand that the decision of the arbiter should be enforced, yet as soon as he had access to the bottomless purse of the State he must become subject to the discipline of political decisions. Sir Hugh did not quarrel with the assertion of Mr. Bevan that, subject to the control of the House of Commons, he must retain control of these decisions, but there was a difference, as between the two sides, in arbitrations under the Bill. If the employer wished to insist on arbitration he could, under the clause, see it was made compulsory, whereas the employed could not insist that a grievance should be the subject of arbitration and that the arbitration should be put into force unless the employer consented. That was inherently unfair and undesirable. The medical profession had understood it had received a promise from Mr. Bevan that it would have a right to insist on arbitration equal with the right of its employers. It seemed to Sir Hugh

that Mr. Bevan had not fulfilled those terms, and the Committee should inquire how Mr. Bevan proposed that doctors, nurses, and all concerned were to be treated fairly in the fixing of their conditions of service. *Sir Hugh* asked if the clause meant that either side could refuse an arbitration, or that only the Minister could do so. He believed that the latter was the case.

Mr. LINSTEAD said it was a good thing to take negotiations on salaries out of the hands of the Minister, so that the Minister would be removed from day-to-day friction with the people with whom he was concerned.

No Compulsory Arbitration

Mr. BEVAN said he did not attach undue weight to the adjectives contained in the resolution of the conference of the British Medical Association. That was a very adjectival body, incapable of passing a resolution except in terms of hyperbole. It did not intend every word to be taken seriously. He could tell a tale of procrastination which would show he was the most badly used man in Britain. Part of the difficulty of the Ministry was to get the members of the medical profession to act with more expedition. Their machinery was so cumbrous that months passed before any decision was received from them. Their negotiating committee was never entrusted with negotiating powers, and the profession had prided itself that the negotiating committee had no power to settle with the Minister. Mr. Bevan said he had tried to come to a conclusion on specialists' terms of remuneration, but month after month went by and the profession was quite incapable of reaching a decision. The clause merely enabled machinery to be set up under the two Acts to which the clause referred. Once it had been accepted and the medical profession had joined the Whitley machinery, disputes would be settled in accordance with the Acts. In these there was no provision for compulsory arbitration, nor did Mr. Bevan think that there should be. Negotiations still continued on the agreement under which doctors would share in the Whitley machinery. There could be no charge of breach of faith until a conclusion had been reached, and the letter of Sir Lionel Whitby should not have been written in such terms. The difficulty was that professional persons reached precipitate conclusions and rushed into the Press.

The October, 1947, proposals to which Sir Lionel drew attention did not differ from what Mr. Bevan had said on the previous day. Mr. Bevan declared that he had not altered his statement that a code of conduct was unlikely to be arbitrable, but a simple proposal for a change in wages or salaries almost certainly was arbitrable. Under the two Acts mentioned in the clause mutual consent was necessary before arbitration. He could not take the medical profession to arbitration if it did not wish to go, nor could the profession take him if he did not desire to go. If arbitration were known to be at the end of the road from the beginning, then all would go to arbitration straight away. Instead of talking about arbitration in every case the Ministry should negotiate with the representatives of the medical profession the terms to be agreed. The medical profession should come forward from time to time with their proposals and try to settle them by negotiation. If that was not possible, they and the Ministry should decide what means could be adopted to reach a mutually acceptable conclusion. Those means might not be arbitration. It might be better to have an inquiry or to refer matters to a quasi-judicial professional body for consideration and statement of principles. He wanted to leave the question as open as possible. He appreciated that discussion on the point had been necessary.

Mr. HOWARD said Mr. Bevan had complicated the matter by saying that in arbitration procedure it was necessary to agree on what was to be referred. If Mr. Bevan would give a clear assurance that either party should have the right to refer an unsolved matter to a second independent and impartial body he would receive the whole-hearted support of all professional men and women.

The Industrial Court and the N.H.S.

Mr. BEVAN pointed out that the Minister of Labour was the person concerned under the Conciliation Act. Section 2 of that Act envisaged a battery of agencies by means of which settlement might be brought about by mutually agreed arbitration, and he did not think there was any reason to apprehend that this elaborate machinery would fail. He added that the Government desired to establish a special division of the Industrial Court to deal with the National Health Service and so to create a body of people with special knowledge of that service which would eventually obtain the confidence of everyone concerned. The Minister of Labour would ensure that those appointed had experience of other fields of arbitration. In very few instances would regulations be needed to give effect to any decisions. Only three situations could ultimately arise. The applicants could withdraw their application, in which case the original situation would be revived. They could agree to arbitration. They could agree to accept the Minister's fiat. These were the limitations of reality. No machinery could be more flexible than that which he had described. If the representatives of the profession got themselves into a position where they could only have recourse to arbitration or accept the decision of the Minister, that would be defective negotiation.

Mr. ELLIOT asked whether there was not a fourth course open to the applicants—withdrawal of labour.

Mr. BEVAN suggested there was not, and that members would not believe that a set of professional workers who had been offered arbitration would prefer to strike rather than to accept it. To cease work would be the abandonment of all machinery.

Dr. HADEN GUEST said Mr. Bevan had put his finger on the spot when he talked of special machinery. The machinery devised for the call-up of doctors for war service, working by conciliation, understanding, and agreement, had done most valuable work. A parallel kind of machinery should deal with the special difficulties of the medical profession. In very few cases would arbitration have to be considered.

Mr. ELLIOT referred to Sir Lionel Whitby's letter and said it was the Minister's business to see that such misunderstandings did not arise.

Mr. BEVAN said it was ridiculous to say that the duty of the Minister was to remove misunderstandings on the benches opposite. In some cases a neurologist would be required—not a Minister.

Mr. ELLIOT suggested Mr. Bevan was thinking of a psychologist—not a neurologist. The apprehension had been left not only in the mind of the president of the British Medical Association but in the mind of the Association itself.

Mr. BEVAN asked whether the Opposition desired compulsory arbitration in all cases. Compulsory arbitration was not in the Whitley machinery. A misunderstanding had arisen in the mind of the medical profession: they had confused temporary war legislation with pre-war Acts and with the machinery which the Government was setting up.

Mr. ELLIOT said it was a great pity that as late as June 20 of this year the negotiating body should still be in doubt over what had been proposed to them as long ago as October, 1947. The Minister had just said that a simple proposal for a change in wage or salary rates was almost certainly arbitrable. That was bound to reassure those who had read Mr. Bevan's declaration of the previous day that the fixing of fees in certain circumstances was not a matter on which the Ministry could agree beforehand to go to arbitration. The Minister apparently had in mind that some other proceeding might be applicable, but those who had read his statement could easily take it to mean "I will make a decision and announce it."

Mr. BEVAN said that if clarity was needed by members of the medical profession they could easily obtain it by entering into an agreement with the Government under the Whitley machinery when the clause was part of the Act. This was an enabling clause, and what would be done under it was a matter for negotiation between the Government and the representatives of the medical profession.

Mr. ELLIOT said that in practice the medical profession had been able to work such things very well. The setting up of a committee to decide under what circumstances the Conscription Acts should apply to them had been a shining triumph of voluntary co-operation. In the present matter the medical profession was in a position where they had to negotiate with an all-powerful employer who could legislate. That employer was negotiating with a body of employees who had declared

that under no circumstances would they ever go on strike. The profession desired the assurance, and had that day received a certain amount of it, but it was undesirable that the Minister should deal with the point about procrastination and not with the point about breach of faith. The doctors were negotiating under different circumstances to those of any other profession. Men who held in their hand life and death could not go on strike, and therefore at the end of the day must fling themselves upon the compassion of the Minister.

Mr. BEVAN said that under the 1946 Act the doctors were not in contract with the Crown, but with the regional hospital boards and executive councils. The Minister could not be indifferent to the demands made upon the Chancellor of the Exchequer over so wide a field. He asked Mr. Elliot to say whether he thought that in this field there should be compulsory arbitration.

Mr. ELLIOT replied that everyone who had spoken on the Opposition side had said "No," and he too said "No." What the Opposition was trying to do was to secure for the benefit of the Service something to replace compulsory arbitration, which all sides agreed it was not possible to use. The suggestion of Mr. Bevan that it was desirable to create a special section of the Industrial Court concerned with the National Health Service was an advance, but he begged him to consider that the necessity for a reassurance still remained.

The clause was then ordered to stand part of the Bill without a division.

Resumption of Practice

On the motion that Clause 13 (removal from lists of persons who do not provide services) stand part of the Bill Mr. LINSTEAD asked what assurance a dental practitioner had that if he was taken off the lists on ceasing to provide dental services for persons in that area he would be replaced on the lists when he resumed the provision of such a service. In the clause it looked as though someone who had been disqualified would not have the automatic right of returning to the list when he resumed practice.

Mr. BEVAN said that if such a practitioner wished to come back he could have his name put up—an illustration of the fact that the Minister had got to take him but that he was not bound to come.

Sir HUGH LUCAS-TOOTH asked whether the clause would not be used as a means of disqualifying practitioners who wished to take only a small share in the public service.

Mr. BEVAN replied that the executive councils had reported that it was confusing when general practitioners who left the district entirely or did not practise at all still had their names up, and the Ministry had no way of removing these names.

Mr. LINSTEAD said he understood that what the Minister said meant that a man's name was removed but that he was not disqualified. Mr. BEVAN indicated assent to this, and Mr. LINSTEAD said he was satisfied. The clause was then ordered to stand part of the Bill, as were Clauses 14 and 15.

Mr. BEVAN, proposing a new clause concerned with the superannuation of officers of certain hospitals, explained that the Ministry had contracts of service with hospitals which did not come within the ambit of the National Health Service but of which he wished to make use. Such hospitals found it difficult to get staff because people who went outside the National Health Service lost their superannuation rights. This clause was read a second time and added to the Bill.

Mr. BEVAN then proposed a further new clause concerned with superannuation of certain officers of Government departments. He said that the Government desired to have the utmost mobility within the Government service, so that doctors could move freely about in that service, particularly in the case of the Colonial service. The peculiar situation was arising that because of the success of preventive health services in countries like Great Britain many doctors had not as much clinical experience as formerly of epidemic diseases. The Government desired that they should be able to take part in the Colonal medical service and come back to the National Health Service carrying with them their superannuation rights. This clause was added to the Bill, and the Committee adjourned until July 5.

London Waiting-lists

Answering Mr. PLATTS-MILLS on June 23 Mr. BEVAN furnished these waiting-lists of the London Regional Hospital Boards. He added that a very large proportion of the waiting-lists consisted of ear, nose, and throat cases, the majority of them awaiting tonsillectomy.

	Medical	Surgical	Ear, Nose, and Throat	Tuber-culosis	Others	Total
N.W. Metropolitan	1,150	14,386	7,000	1,438	483	24,457
N.E. Metropolitan	453	9,344	6,259	1,053	4,172	21,286
S.E. Metropolitan	617	5,719	10,129	1,128	5,709	23,293
S.W. Metropolitan	853	7,934	8,032	1,098	3,066	21,033
						90,069

Non-paying Patients in Pay-Beds.—Mr. COLLINS asked Mr. Bevan on June 23 to draw the attention of Regional Hospital Boards to the importance of ensuring that priority in the allocation of private wards was given to non-paying patients who were in need of privacy on medical grounds. Mr. BEVAN said his information was that Boards already followed this practice. In 69 hospitals having 847 private pay-beds, 342 were at the time of his inquiry occupied by non-paying patients on medical grounds.

Universities and Colleges

UNIVERSITY OF LONDON

A Special University Lecture on "Normal and Pathological Physiology of the Kidney" will be delivered by Donald D. Van Slyke, Ph.D., Sc.D. (Rockefeller Institute for Medical Research), at the London School of Hygiene and Tropical Medicine, Keppell Street, W.C., on Monday, July 18, at 5.30 p.m.

The degree of Ph.D. in the Faculty of Medicine (Non-clinical) has been awarded to S. De, M. A. El Meheiri, S. El D. M. Salama, A. S. Sinha, S. Manheim.

UNIVERSITY OF WALES

The following candidates for the degrees of M.B., B.Ch. at the Welsh National School of Medicine have satisfied the examiners at the examination indicated:

PATHOLOGY AND BACTERIOLOGY.—D. F. Brown, Josephine J. Candy, L. M. Charles, D. E. Copas, B. M. Davies, Ifid M. L. Davies, *J. M. S. Dixon, J. L. A. Dowse, D. R. T. Evans, D. W. Evans, J. Evans, B. M. Frost Smith, B. J. Fudge, S. G. Gang, Nansi G Gwynne, A. J. Hooper, D. T. Jones, Mary E. V. Jones, J. Magell, T. M. Morgan, W. B. Morgan, E. D. Morris, T. L. Morris, D. Phillips-Miles, Dilys Rees, J. W. Rees, D. B. Scourfield, A. P. Thomas, Margaret E. Thomas, Margaret H. J. Thomas, Anne G. Tighe, D. S. Wood.

*With distinction.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council held on June 17 the following appointments were made: *Part-time Lecturer in Neurology and Clinical Teacher:* James Carson, M.B., M.R.C.P. (to be held concurrently with his part-time Lectureship in Psychology). *Part-time Clinical Teachers in Medicine:* K. J. G. Milne, M.D., D.P.H., E. G. G. Rhind, M.B., Ch.B., M.R.C.P. *Part-time Clinical Teachers in Surgery:* J. T. Chesterman, F.R.C.S., F.A.C.S., F. J. P. O'Gorman, F.R.C.S.Ed., M.R.C.O.G., S. Pappworth, M.B., M.Ch.(Orth.). *Part-time Lecturer in Obstetrics and Gynaecology and Clinical Teacher:* David H. Lees, F.R.C.S.Ed.

UNIVERSITY OF BRISTOL

J. S. Baxter, M.A., M.Sc., M.D., F.R.C.S.I., Senior Lecturer in Anatomy, has been elected Reader in Anatomy in the University, from Aug. 1.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Mr. Norman Shenstone, M.D., Hon.F.R.C.S., will deliver the Tudor Edwards Lecture at the College (Lincoln's Inn Fields, London, W.C.) on Wednesday, July 13, at 5 p.m. His subject is "The Treatment of Bronchiectasis."

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 18. [No. 24

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales, Eire, and Northern Ireland.

EPIDEMIOLOGICAL NOTES

Paratyphoid Fever in North Durham

Since the beginning of June eighty-one infections with *S. paratyphi-B* have been recognized in North Durham. All those so far tested have been phage type 3a. The infections fall into two main groups. In the Jarrow-Hebburn-Boldon area 74 cases have been investigated. The first case occurred on May 25, and the majority of clinical cases began during the following week. The severity of the disease has varied considerably. In 10 patients the illness was moderate to severe and the condition of three gave rise to anxiety, though there have been no deaths. In the remainder the disease has been mild or trivial; and in nearly half there were no symptoms, the infection being recognized only in the course of examination of contacts. Cream cakes appear to have been the cause of the primary infections. Two symptomless infected persons have been detected in the bakery concerned, though it is not yet known whether they are true carriers or recent infections. One of these, a baker who makes the cream cakes, excreted the organism in his urine. It appears that the primary source of infection has ceased, but further secondary cases are probable, since the cakes believed to have been infected had a wide distribution. In the Sunderland area seven infections have been recognized in five families. No connexion has been established between these families and those infected in the Jarrow-Hebburn outbreak, and no vehicle of infection has been discovered. Variations in the clinical picture have been similar to those found in the Jarrow-Hebburn outbreak. There have been no deaths.

Poliomyelitis in Cornwall

Twelve cases of poliomyelitis have been notified during the last 14 days (up to July 4) in the Redruth-Camborne urban district. Eight of these cases were from the village of Illogan, four in one family. Only five of the patients have developed paralysis, and one child, aged 2½, has died. Of the 12 cases so far notified, nine are in the 1–5 age group.

Quarterly Returns for Scotland

The birth rate during the March quarter of 1949 was 19.0, being 0.8 below the rate for the first quarter of 1948. The infant mortality rate of 50 per 1,000 registered live births was 1 below the rate for the corresponding quarter of the preceding year and 15 below average of the first quarters of 1944–8. The general death rate at 15.1 per 1,000 was 2.0 more than in the first quarter of 1948 and 0.3 above the average of the five preceding March quarters. There were 356 deaths attributed to the principal epidemic diseases, the largest totals being 280 from influenza, 45 from whooping-cough, 14 from cerebrospinal fever, 7 from measles, and 6 from diphtheria. The death rate from all forms of tuberculosis was 78 per 100,000 and from respiratory tuberculosis 70. The former rate is the same as that for the first quarter of 1948, but the latter is 4 more than the corresponding figure for 1948. These rates were respectively 4 less and 5 more than the average of the five preceding first quarters.

Discussion of Table

In *England and Wales* there was an increase in the number of notifications of whooping-cough 447, acute poliomyelitis 18 and paratyphoid fever 14. There were decreases in the incidence of scarlet fever 160 and measles 97.

The largest increases in the notifications of measles were London 107 and Lancashire 98; the largest decreases were Derbyshire 134 and Kent 104. A fall occurred in the incidence of scarlet fever in all areas except the south-eastern counties, where there was a slight rise; the largest fall was 46 in Lancashire.

The chief feature of the returns for diphtheria was an increase of 6 in London. The largest rises in the incidence of whooping-cough were Lancashire 99 and Yorkshire West Riding 53.

A further 28 cases of paratyphoid fever were notified from the outbreaks in Durham, referred to above, where 15 cases

were reported last week. The largest returns during the week were Jarrow M.B. 13 and Hebburn U.D. 7.

A small decrease in the incidence of dysentery was recorded in every area except Lancashire. The rise there was due to the experience of Liverpool C.B., where the cases increased from 8 to 26.

In the rural district of the Isle of Wight 82 cases of food poisoning were notified. A further 25 cases of food poisoning were notified in Northumberland, Hexham U.D.; 25, 4, and 24 cases have been notified in this town during the past three weeks.

In *Scotland* decreases were recorded in the notifications of measles 157, whooping-cough 27, and dysentery 22; an increase was reported for scarlet fever 16. The decrease in the incidence of dysentery was due to the city of Glasgow, where the cases notified fell from 34 to 18.

In *Eire* increases occurred in the notifications of measles 42, whooping-cough 24, scarlet fever 11, and diarrhoea and enteritis 23. The largest of the fresh outbreaks of measles was at Kerry, Listowel R.D. 49. In Dublin C.B. notifications of measles were 36 fewer than in the preceding week, but an increase was recorded for other infectious diseases in this city.

In *Northern Ireland* increases were reported in the notifications of whooping-cough 20, scarlet fever 9, and diphtheria 7, with a decrease of 27 in the incidence of measles.

Week Ending June 25

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,137, whooping-cough 2,181, diphtheria 73, measles 6,863, acute pneumonia 334, cerebrospinal fever 26, acute poliomyelitis 48, dysentery 66, paratyphoid 31, and typhoid 8.

The Services

Major-General K. A. M. Tomory, C.B., O.B.E., late R.A.M.C., has been appointed Honorary Physician to the King in succession to Major-General W. Foot, C.B., M.C., who has retired.

DEATHS IN THE SERVICES

Colonel ALFRED ROSENBLOOM, late I.M.S., died on June 1 at the age of 47. A native of Edinburgh, he graduated M.B., Ch.B. there in 1923 and took the Liverpool D.T.M. in 1929. In 1925 he joined the Indian Medical Service, and he retired in 1947 with the honorary rank of colonel. He leaves a widow and two young children.

Lieut.-Colonel E. J. Curran writes: His many friends in the Services will learn with much regret of the recent death of "Rosie" or "Blossom," as he was known to many of us. A cheerful kind-hearted man who loved his work, he was popular alike with colleagues and patients and was always prepared to give of his best. We have lost a good comrade and reliable colleague.

Surgeon Rear-Admiral WILLIAM WALLACE KEIR, who was formerly in charge of the Royal Naval Hospital at Haslar, died on June 12 at the age of 72. A student at Glasgow University, he graduated M.B., Ch.B. in 1898. During the early part of the 1914–18 war he was medical officer of the minelayer *Iphigenia*. He served at Jutland in the *Warspite*, and from December, 1916, he was senior medical officer of the hospital ships *Rewa* and *China*. He was made a C.M.G. in 1918 and was a Chevalier of the Legion of Honour. After the war Keir was squadron medical officer of the First Battle Squadron and the Battle Cruiser Squadron, and was later in charge of the hospital ship *Maine*. After service in China in charge of the Hong Kong Naval Hospital, he was transferred in 1932 to the Royal Naval Hospital at Haslar, where he succeeded Surgeon Rear-Admiral H. C. Whiteside. In 1934 he was appointed honorary surgeon to the King, and he retired in 1935.

The National Office of Vital Statistics in the U.S.A. has recently reported that the maternal mortality rate for the United States in 1947 was 1.3 per 1,000 live births. This is said to be the lowest reported for any nation. The State with the lowest rate (0.6 per 1,000 live births) was Minnesota.

Medical News

Nuffield Professor of Orthopaedic Surgery

Dr. Joseph Trueta has been appointed Nuffield Professor of Orthopaedic Surgery in the University of Oxford.

Dr. Trueta, who is 51 years old, was born in Barcelona and graduated at the University of Barcelona in 1921, proceeding M.D. the following year. In 1933 he was appointed assistant professor of surgical pathology in the University, and in 1935 succeeded Professor E. Ribas-Ribas as Chief Surgeon to the Hospital de la Santa Creu i Sant Pau, Barcelona, bearing the title of Professor of Surgery. During the Spanish Civil War he gained wide experience there in the treatment of casualties, and developed the closed-plaster technique of treating compound fractures. He came to Britain in 1939, and since then has been working at the Wingfield-Morris Orthopaedic Hospital at Oxford and hospitals associated with it. In 1940 he was appointed to the staff of the Wingfield-Morris Hospital in the capacity of adviser to the Ministry of Health, and from 1942 to 1944 he was in charge of the accident service at the Radcliffe Infirmary, Oxford. Oxford University made him an additional Member of the Faculty of Medicine in 1949. Among his earliest papers on war surgery published in this country was "War Fractures Treated by the Closed Method," which appeared in the *British Medical Journal* of Dec. 2, 1939 (p. 1073). More recently he has studied the renal circulation, and in particular the vascular short-circuiting mechanism and its relation to cortical ischaemia. This work was recorded in a monograph, *Studies of the Renal Circulation*, by himself and his colleagues published in 1947.

Guy's Hospital Honours Lord Nuffield

Lord and Lady Nuffield were present at Guy's Hospital on June 29, when Lord Goschen unveiled a statue of Lord Nuffield by Mr. Maurice Lambert. This was the outcome of a resolution by the Court of Governors in 1944 to mark "their profound appreciation of his manifold benefactions to the hospital, of his inestimable services as its treasurer, and of his never-failing interest in the progress of medicine." The cost of the statue was met by subscriptions limited to the governors and staff of Guy's and to men and women trained there. The intention is that the statue will stand in the new hospital, but in the meantime it has been placed in the west quadrangle. The ceremony was performed in the presence of many distinguished visitors and of large numbers of nurses, students, patients, and their friends. In his speech Lord Goschen thanked Lord Nuffield for his many benefactions to Guy's, among them his gift of £250,000 for rebuilding, and for his services to medicine. In reply Lord Nuffield said that in his travels he had found that Guy's Hospital was renowned throughout the world.

R.A.M.C. Book of Remembrance

The Book of Remembrance, which records the names of 437 officers and 2,026 other ranks of the Royal Army Medical Corps killed in the second world war, was dedicated by the Dean of Westminster at Westminster Abbey on June 27. The ceremony, which took place after evensong, was held beneath the R.A.M.C. window which was unveiled in 1922. Among those present were Lieutenant-General Neil Cantlie, Director-General Army Medical Services, and officers and other ranks of the R.A.M.C.

Recognition for Bravery

The *London Gazette* has announced the appointment as M.B.E. (Civil Division) of Dr. W. J. L. Sladen, Medical Officer, Falkland Islands Dependencies Survey, for courage and fortitude in hazardous circumstances when isolated in Graham Island.

Bilharzia Film

Two films about bilharzia were shown at the London School of Hygiene on June 30. Professor G. Macdonald introduced Mr. K. M. Goodenough, the High Commissioner for S. Rhodesia, who explained that the films had been prepared by the Health and Public Relations Departments of the Government

of S. Rhodesia. The first film, "The African Schistosomiases," was intended for the instruction of doctors and health workers, while the second film, "Still Waters," was for public education. In both films emphasis is placed on the prevention of infection. "The African Schistosomiases" runs for about fifty minutes and gives a full account of the life cycle of the parasites, the pathology of the disease, methods of laboratory investigation, treatment, and prevention. "Still Waters" is a shorter film, illustrating in a convincing way, with the help of actors, the dangers of carelessness and the precautions which should be taken to avoid infection.

British Doctors Honoured in New York

At the banquet of the Seventh International Congress on Rheumatic Diseases held at the Waldorf-Astoria in New York recently the following were presented with Diplomas of Honorary Membership of the American Rheumatism Association: Dr. C. W. Buckley, Dr. J. B. Burt, Dr. D. H. Collins, Dr. W. S. C. Copeman, Professor L. S. P. Davidson, Dr. J. A. Glover, Lord Horder, Dr. G. D. Kersley, and Dr. W. Tegner.

Wills

Dr. Louisa Hamilton, who was senior physician to the Elizabeth Garrett Anderson Hospital, left £21,169. Dr. Hugh Mundle Wilson, of Linton, Cambs, left £10,500; Dr. William John Young, of Kempston, Beds, £7,137; Dr. Matthew McLintock Bainbridge, of Birmingham, £2,283.

COMING EVENTS

Maternal and Child Health in India

A lecture on this subject will be given by the Hon. Rajkumari Amrit Kaur, Minister of Health to the Government of India, at the Royal College of Obstetricians and Gynaecologists, 58, Queen Anne Street, London, W.1, on Monday, July 11, at 5 p.m. Admission is by ticket only; these can be obtained from the secretary.

Netherne Psychiatric Hospital

An exhibition of paintings by patients of Netherne Psychiatric Hospital, Coulsdon, Surrey, will be formally opened by the Countess of Limerick at 1, Grosvenor Crescent, Hyde Park Corner, London, S.W., on Monday, July 11, at 12 noon. The exhibition will remain open until July 16, from 10.30 a.m. to 4.30 p.m. daily (Saturday, 10.30 a.m. to 12 noon). A lecture will be given each day at 3 p.m.

Osler Club

A dinner will be held by the Osler Club at the Royal College of Surgeons on July 12 at 7.15 p.m. for 7.30. Mr. Gilbert Frankau will deliver the Oslerian Oration on "Are We Over-doctored?—A Centennial Reflection."

International Congress of Otolaryngology

The fourth International Congress of Otolaryngology will be held at King's College, Strand, London, W.C., from July 18 to 23, and will be opened by the Duchess of Kent on Monday, July 18, at 11 a.m.

SOCIETIES AND LECTURES

Monday

LONDON UNIVERSITY: INSTITUTE OF CHILD HEALTH.—At Hospital for Sick Children, Great Ormond Street, London, W.C., July 11, 5 p.m., "*The Artificial Kidney*," Alexander Simpson-Smith Lecture by Professor Gordon Murray, Associate Professor of Surgery in the University of Toronto.

Tuesday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., July 12, (1) 11 a.m., "*Urethritis due to Protozoa, Metazoa, and Fungi*," by Dr. A. H. Harkness; (2) 5 p.m., "*Hydatid Disease and Bilharzia of the Urinary Tract*," by Mr. R. Ogier Ward.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.—July 12, 5 p.m., "*The Role of the Aged in Modern Society*," F. E. Williams Lecture by Dr. J. H. Sheldon, F.R.C.P.

SOCIETY FOR THE STUDY OF ADDICTION.—At Medical Society of London, 11, Chandos Street, W., July 12, 4 p.m., "*The Alcohol Problem in Switzerland*," by Dr. Henri Revilliod (Geneva).

Wednesday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., July 13, (1) 11 a.m., "*Traumatic Urethritis*," by Dr. A. H. Harkness; (2) 5 p.m., "*Stricture of the Urethra*," by Mr. J. E. Semple.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—July 13, 5 p.m., "*The Treatment of Bronchiectasis*," Tudor Edwards Lecture by Mr. Norman Shenstone, M.D., Hon.F.R.C.S.

ROYAL SANITARY INSTITUTE.—At 90, Buckingham Palace Road, London, S.W., July 13, 2.30 p.m., Discussion: "*Health Centres*," to be opened by Dr. J. A. Scott, W. J. Durnford, F.R.I.B.A., and Dr. A. Talbot Rogers.

Thursday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., July 14, (1) 11 a.m., "*Ureteritis Due to Local Diseases of the Penis*," by Dr. A. H Harkness; (2) 5 p.m., "*Gonococcal Urethritis*," by Dr. W. N. Mascall.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—At Royal Society of Medicine, 1, Wimpole Street, London, W., July 14, 5 p.m., "*Caudal Anaesthesia*," by Professor R. A. Hingson (Johns Hopkins Hospital, Baltimore). Admission by ticket only.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—July 14, 5 p.m., "*Adventures in Metabolism*," Bernhard Baron Lecture by Professor John Beattie, M.D.

Friday

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—July 15, Part I, 3.45 p.m., "*Odontogenic Tumours of the Jaws*," Part II, 5 p.m., "*Osteogenic Tumours of the Jaws*," Charles Tomes Lecture by Professor Kurt Thoma (President, American Academy of Oral Pathology).

ROYAL SANITARY INSTITUTE.—July 15, 10.15 a.m., Visits to Messrs. Boots Pure Drug Co.'s Works at Beeston and to sewage disposal works and farm at Stoke Bardolph; 2.15 p.m., At the Guildhall, Nottingham, "*Atmospheric Pollution—the Present Position and Outlook for the Future*," by Alfred Wade; "*Sewage Disposal in Nottingham—Some Recent Developments*," by Hugh Lawson, B.Sc.

APPOINTMENTS

NEWNHAM, C. T., M.R.C.S., L.R.C.P., D.O.M.S., Medical Officer, Western Region, British Railways.

ST. ANDREW'S HOSPITAL, BOW, LONDON, E.—*Senior Resident Physician*, R. King Brown, M.D., M.R.C.P. *Assistant Specialist, Obstetrician and Gynaecologist*, S. Lask, M.D., M.R.C.O.G.

WEST, R., M.R.C.S., L.R.C.P., D.P.H., *Medical Officer* to the National Dock Labour Board's Medical Scheme for the Humber Ports.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Byrne.—*On June 17, 1949*, to Ruth (née Marle), wife of John W. Byrne, M.B., B.Ch., B.A.O., of The Barn, Rush Hill, Bath, a brother for Simon—Jeffrey Patrick.

Fiddian.—On June 26, 1949, at Warwick Hospital, to Audrey (née Maslin), wife of Dr. M. P. Fiddian, a son—Colin Paul.

Majury.—*On June 16, 1949*, at Johnstone House, Belfast, to Margaret (née Huss, S.R.N.), wife of Dr. Arthur S. Majury, a daughter.

Neve.—*On June 25, 1949*, at Guy's Hospital, to Elizabeth (née Hunt), wife of Richard Neve, M.B., B.S., a sister for Michèle.

Playfair.—On June 27, 1949, at Cambridge, to Margaretta (née Blakeston), wife of Dr. A. S. Playfair, a brother for David and Rodney—Quentin.

Smith.—*On April 30, 1949, in Singapore*, to Thorven, wife of Mr. T. E. Smith, a daughter.

MARRIAGES

Shield—Wood.—On June 3, 1949, at St. John's Presbyterian Church, Kensington, London, James Boyd Shield, M.B., F.R.C.S.Ed., Southampton, to Margaret Hay Wood, Aberdeen.

Zetzel—Guttmann.—On June 26, 1949, in London, Dr. Louis Zetzel, of Boston, Mass., U.S.A., to Elizabeth Guttmann (Dr. Elizabeth Rosenberg), widow of Dr. Eric Guttmann.

DEATHS

Lane.—*On June 20, 1949*, at Chevers Lodge, Ballybunion, Co. Kerry, Daniel Thomas Lane, M.D., Lieutenant-Colonel I.M.S., retired.

McAfee.—On June 13, 1949, at West Kirby, Duncan John McAfee, M.C., M.B., Ch.B., aged 63.

Maurice.—On June 19, 1949, at Manton Weir, Marlborough, Godfrey Kindersley Maurice, D.S.O., M.C., M.R.C.S., L.R.C.P., Colonel late R.A.M.C., aged 62.

McCarter.—On June 8, at the Royal Portsmouth Hospital, William Harold Raphael McCarter, M.B., B.Ch., of East Cottage, Hurstpierpoint, Sussex, late of Burgess Hill.

Mullings.—On June 12, 1949, William Thomas Mullings, M.D., of 27, Compayne Gardens, London, N.W., formerly of 84, Belgrave Road, London, S.W., and Dunsfold, Godalming.

Murray.—*On June 19, 1949*, at Bridge of Earn Hospital, Archibald C. Murray, M.B., Ch.B.

O'Malley.—On June 22, 1949, at Wharfedale, Canterlupe Road, Bexhill-on-Sea, John Francis O'Malley, M.Ch., F.R.C.S., aged 80.

Purves-Stewart.—*On June 14, 1949*, at 45, Edwardes Square, London, W., Sir James Purves Morison Purves-Stewart, K.C.M.G., C.B., M.D., F.R.C.P., aged 79.

Thwaites.—On June 10, 1949, at Old Acres, Ashtead, Surrey, Cyril Evered Thwaites, M.R.C.S., L.R.C.P., aged 74.

Any Questions ?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Hypertension and Functional Menorrhagia

Q.—*Is there any relationship between hypertension and the functional menorrhagia of the menopause? Could you please quote references?*

A.—There is no work on record which establishes the existence of such a relationship or which goes to show that hypertension alone ever causes any form of uterine haemorrhage. The idea was popular in the early part of this century, and throughout the literature of that time are phrases such as: "The significance of functional hypertension as a factor in uterine haemorrhage is obvious" (C. Culbertson, *Surg. Gynec. Obstet.*, 1916, 23, 667). Statements of this kind, however, are not supported by evidence. Although this view has gradually lost popularity and is now rarely mentioned in textbooks, it is difficult to find any reference to investigations which prove that hypertension does not cause uterine bleeding. Nevertheless, in most cases of "functional uterine bleeding" another cause can be demonstrated: a significant association between bleeding and hypertension is not noticeable in everyday practice, and uterine bleeding does not occur at the age when the blood pressure reaches the highest levels, therefore, after the menopause.

It might be argued that uterine haemorrhage may result if the hypertension is associated with arteriosclerosis affecting the uterine vessels. This again is an old view which was the basis of numerous articles earlier this century. Many of these were reviewed by E. Novak in *Menstruation and Its Disorders* (Gynaecological and Obstetrical Monographs) in 1921, and he concluded then that "no evidence has as yet been presented which, to my mind, justified us in ascribing more than an occasional role to this cause." Nor has such evidence been produced since that time.

Adrenaline and Blood Pressure

Q.—*Does the blood pressure rise or fall following the use of compound adrenaline injections, tablets, or inhalations for asthma? One preparation is advertised as causing a slow rise in blood pressure, whereas another is said to cause a rise rarely and a fall ordinarily. What is the effect of the isopropyl-noradrenaline compound?*

A.—Adrenaline when infused intravenously causes some rise of systolic pressure and some fall of diastolic pressure, as shown recently by Barcroft and Konzett (*Lancet*, 1949, 1, 148). When injected subcutaneously adrenaline has little effect on the blood pressure, and what effect there may be is similar to that of intravenous infusion. Given as a tablet by mouth, or when inhaled as a spray, adrenaline has no effect on the blood pressure as a rule. Isopropyl-*nor*-adrenaline causes a fall of blood pressure even when injected intravenously.

Estimating Basal Metabolic Rate

Q.—*Is Read's formula for estimating the basal metabolic rate reasonably accurate? Are there any other methods of estimating the B.M.R. without cumbersome and expensive apparatus?*

A.—For many years attempts have been made to find a mathematical correlation between pulse pressure and pulse frequency on the one hand and basal metabolism on the other. The earliest formula devised was that of Read (*J. Amer. med. Ass.*, 1922, 78, 1887). He claimed that if PR is the pulse frequency in beats per minute and PP the pulse pressure in millimetres of mercury, the expression 0.683 (PR+0.9 PP)−71.5 provided a figure which was within 20% of the basal metabolic rate (B.M.R.) in 91% of cases and within 10% in 60% of cases. Two years later he modified his formula to 0.75 (PR+0.74 PP)−72, and claimed that the result of this estimation was within 10% of the correct value in over 50% of cases (*Arch. intern. Med.*, 1924, 34, 553). Read's data were subjected to statistical analysis by Gale and Gale (*Lancet*, 1931, 1, 1287), who tested six different formulae and concluded that PR+PP−111 gave the best correlation, with an error not exceeding 20% in 74% of cases. From a study of his own records, Jenkins (*Arch. intern. Med.*, 1932, 49, 189) suggested that, for males, 0.534 PR+0.436 PP−62.55 and, for females, 0.75 PR+0.57 PP−72 gave the best fit, with a probable error of 9.9% when the Aub-DuBois standards of basal metabolism were used. Bene (*Lancet*, 1949, 1, 147) has raised the subject again by claiming that a more reliable guide is given by his "RP-Index." To obtain this the pulse and respiratory frequencies per minute are multiplied; the normal range is 1,100–1,500, with a mean of 1,296. The observed RP-Index, when stated as a percentage of the mean normal, lies within 10% of the B.M.R. in about 60% of cases.

These observations prove that there is an imperfect correlation between the B.M.R. and the pulse frequency and pressure. The figures given by the various formulae may give numerical expression to the degree of thyrotoxicosis in a rough fashion, but they are no substitute for careful and accurate estimation of the basal metabolism. In practice the B.M.R. estimation is useful in two situations: first, to confirm the diagnosis when some doubt exists; and, secondly, as a guide to progress. The formulae do not give a sufficiently exact correlation for diagnostic purposes and the patient's progress can usually be assessed by changes in his clinical state, pulse frequency, and weight. Thus Read's formulae and their successors never provide information to which much importance can be attached and if it seems desirable to know the patient's B.M.R. it must be estimated in the usual fashion.

Whooping-cough Vaccine

Q.—*Is it necessary to give booster doses of pertussis vaccine? If so, at what intervals, and in what doses?*

A.—If it is assumed that prophylactic vaccination is effective against whooping-cough, the primary course should be given as early as possible in infancy, since 10 to 20% of children are affected in the first year of life and more than half the deaths occur at this time. Little is known about the value of a booster dose or when it should best be given. Kendrick and his colleagues (*Amer. J. Dis. Child.*, 1946, 72, 383) found that the defence mechanism, as tested by the opsonocytophagic reaction, was similar in groups of kindergarten children who had their primary vaccine one, two, three, or four years previously, and the antibody response to a further injection was the same in all four groups. The pertussis attack rate during the first two years' attendance at school was 0.7% among 408 immunized children who received a booster dose, 1.2% among 418 immunized children who did not receive a booster dose, and 6.4% among 829 children not previously vaccinated. A booster dose of, say, 1.0 ml. of vaccine would therefore seem to have some value and should be given two or three years after the primary course, or when the child goes to school.

Vitamin B_1 in Diabetes

Q.—*The carbohydrate tolerance of a male patient suffering from diabetes mellitus has improved since 10 mg. of vitamin B_1 were added to the morning and evening injections of insulin. How does vitamin B_1 act on the carbohydrate metabolism in a normal person and in a person suffering from diabetes mellitus?*

A.—This experiment has been tried by others without being followed by any reduction in the dose of insulin required. Experiences of this kind, which others have failed to confirm, have been reported with so many different substances that it is important to consider the reasons for the discrepancies. There are two, and possibly more, explanations: (1) The patient's health was improving at the time of the experiment, and this is responsible for the change in the dose of insulin and not the

new treatment. (2) The patient has been much more careful over the carbohydrate ration as a result of the new treatment, and consequently requires less insulin.

Travel in Italy

Q.—*What instructions should be given to a would-be traveller to Italy and Sicily this August, with special reference to (a) drinking tap-water, (b) inoculations, and (c) the possibility of contracting malaria?*

A.—*(a)* Except in the largest towns the drinking of tap-water should be avoided unless it has been boiled previously. *(b)* It would be as well to be inoculated against typhoid and paratyphoid. (c) If the traveller is staying only in the larger towns there is little or no risk of his becoming infected with malaria. If he proposes to stay in small towns or villages or to be in the country in the evenings he should take proguanil 0.1 g. daily during the time that he remains in the country.

Anaesthetics for Domiciliary Midwifery

Q.—*In obstetrics in general practice open ether has the disadvantage of inflammability. To what extent is this a danger—e.g., with open fires, paraffin lamps, etc.? If this is a real contraindication, what is the most satisfactory alternative anaesthetic for single-handed domiciliary obstetrics?*

A.—The danger of using drop-ether in proximity to an open fire is that of burning rather than that of explosion of the ether vapour. Although it is generally stated in the textbooks that a mixture of ether vapour and air is explosive, experts in this field are doubtful whether this is so in ordinary clinical practice. The danger of fire, however, is very real, and is doubly dangerous because the ether vapour burns with an almost invisible flame which may travel some distance without any warning and so set fire to distant inflammable objects. The alternative to ether in domiciliary midwifery is either chloroform or trilene. In view of our pharmacological knowledge of these drugs, trilene seems to be the safer. Adequate analgesia with trilene is easily provided by means of one of the many types of apparatus on the market for the purpose. In one of these (i.e., the Cyprane inhaler) the concentration of trilene inhaled by the patient can be increased, should the anaesthetist desire it, and thus general anaesthesia may be induced. An alternative arrangement is to use any gas–oxygen apparatus and to put the trilene in the ether bottle which is usually to be found on such an apparatus. The strength of trilene vapour delivered from the Freedman inhaler is unlikely (except in patients with very low resistance) to produce general anaesthesia.

Protecting a Stiff Thumb

Q.—*A patient has had an injury which has resulted in ankylosis of the interphalangeal joint of his right thumb. He is a very keen cricketer, and finds now that, although he can hold his bat adequately, his right thumb is exposed to frequent injury while batting. He has asked me whether any metal protectors for fingers which have suffered injury are available, and I could not tell him. Can anything more be done for him?*

A.—This is a problem which can probably best be solved by consultation between the patient and a skilled surgical appliance maker. Almost certainly some suitable protective covering for the thumb could be devised. It is possible that a thumb-stall of relatively soft leather, with steel reinforcement sewn into it along the dorsum and over the tip of the thumb, would be adequate.

Loss of Eyebrows

Q.—*What are the causes of loss of hair from the eyebrows? Is there any effective treatment? A male patient aged 29 has had patchy loss of hair from both eyebrows for the last two months. The patches are absolutely smooth and no broken hair can be seen; the skin in these areas is otherwise normal. There is no itching or soreness.*

A.—This case is almost certainly one of alopecia areata, but the location of the changes makes it important to exclude local factors or irritation, such as infection in adjacent sinuses or teeth or errors of refraction. It is more probable that the affection is merely a reaction in a sensitive patient to some constitutional disturbance following minor infection or metabolic or emotional disturbance. In that event the assessment of the patient in relation to his environment may be important, and the prognosis will be influenced by the patient's past history and family history in relation to alopecia, dermatological affections, and mental health.

It must be remembered that the great majority of cases of alopecia areata are transient and of little significance and recover spontaneously. General treatment is important, and a holiday in new surroundings would probably be beneficial. Local measures are not indicated except perhaps to obscure the bald areas by means of an eyebrow pencil.

NOTES AND COMMENTS

Urticarial Reaction to Penicillin.—Lieutenant-Colonel H. S. ANDERSON, R.A.M.C. (ret.), writes: With reference to the question and answer under this heading ("Any Questions?" *June 4, p. 1016*) the questioner may be interested in a personal experience. In March, 1948, I was given four injections of penicillin; the fourth one was given at my request. Nineteen days later urticaria appeared, was personally treated, and remained troublesome for about five weeks. In September, 1948, I received three injections of penicillin. Urticaria occurred on the thirteenth day, accompanied by strangury and haematuria. I was given an antihistamine drug by mouth for four days, but improvement was noticeable within 24 hours, and urine returned to normal rapidly.

Treatment of Asthma.—Major ERNEST SOYSA (Colombo) writes: The association of asthma and leucocytosis in the case mentioned in "Any Questions?" (April 23, p. 736) raises the interesting possibility of an eosinophilic reaction, even though this patient's previous allergic history may not be typical of the eosinophilic respiratory syndrome common in the Tropics. I have recently seen two similar cases, both patients were Englishmen in whom leucocytosis had been detected a short time previously in London, neither having derived any lasting benefit from various asthma treatments. I had their differential counts done: one had 15,000 leucocytes per c.mm. with 48% eosinophils, and the other had 17,900 leucocytes with 50% eosinophils. Examination of the sputum of one patient by a special technique[1] revealed tyroglyphid mites. Oral medication with pentavalent arsenic (carbarsone 1 tablet b.d. for five days, repeated after an interval of two days) produced the typical dramatic cure in both patients, who showed the Herxheimer reaction reported previously in the *Journal*.[2] A recent review[3] of a series of asthmatic cases (in Ceylon) with eosinophilia ranging from 1,000 to 50,000 cells per c.mm. disclosed occupational and environmental risks of inhaling airborne mites in 80% of the cases. Detection of mites in 62% of the sputum examinations undertaken was suggestive of pulmonary acariasis and confirmed the original findings[1] that led to this line of inquiry. Three series of control cases subjected to identical sputum tests gave negative results. Pathognomonic appearances of the eosinophilic respiratory syndrome were observed in 50% of the pulmonary radiographs studied. The strikingly effective therapeutic action of organic arsenicals was constant. A few workers in other lands have confirmed observations made in Ceylon on the association of this eosinophilic respiratory syndrome with pulmonary acariasis. Further studies of the aetiology and pathology are necessary, and will doubtless be forthcoming, in view of the world-wide interest that appears to have been created in this remarkable malady.

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY JULY 9 1949

British Medical Association

ANNUAL REPRESENTATIVE MEETING, HARROGATE, 1949

TUESDAY, JUNE 28

On the last day the meeting resumed at 9.30 a.m., under the chairmanship of Dr. E. A. Gregg. The first business was to accord a hearty vote of thanks to a number of distinguished persons and organizations who had helped to make the stay at Harrogate so pleasant for the representatives. Those specially thanked included H.R.H. the Princess Royal and the Earl of Harewood, the Mayor and Corporation of Harrogate, and many others who had afforded hospitality and service, not least the doctors of Harrogate and their ladies.

The British Medical Guild

The Chairman of Council (Dr. H. Guy Dain), in reply to a request, described the progress of the British Medical Guild. The Guild had now been properly established. The board of trustees was constituted of members of Council who had signed the trust deed. Arrangements were in process for obtaining financial support. So far as general practitioners in the Service were concerned the method of collection was already in being. It had been referred to the Central Consultants and Specialists Committee and the Public Health Committee to consider the method to be used in those branches of the profession. In each area there would be a branch of the Guild with its own officers, who would be charged with making contact with all members of the profession.

The Record of Representative Meetings

Dr. C. R. Barrington (Bromley) moved that the meetings of the Representative Body should be recorded verbatim as in *Hansard* and be available for reference. His Division was dissatisfied with the length at which the Special Representative Meeting was published in the *Journal*, and thought that, though it would entail more expense, everything said should be recorded.

Dr. Hill (Secretary) said he would offer no opinion as to the desirability of this or the quality of the volume which would emerge, but it would be a very expensive procedure; and it would be unwise on financial grounds to adopt it unless it was thought that the volume would be published and sold in sufficient numbers to justify the expense.

Dr. G. Catherine Evans (East Kent) supported the Bromley proposal. Representatives took a grave responsibility in coming there, and at some future time they might be very thankful—or terribly embarrassed—if their actual words could be quoted.

Dr. Hill suggested that the report as it appeared in the *Journal*, the work of an experienced reporter of Association proceedings, was probably more useful than a verbatim record.

A representative suggested that any alteration should be in the direction of compression rather than extension. Members were apt not to read such proceedings, and the longer the reports the more likely they were to be unread.

Dr. Barrington said he had read reports of meetings which were accurate in wording but misleading in sense; he was casting no aspersions.

About half a dozen hands were held up in support of the Bromley motion, which was lost.

The next two motions were referred to Council. One was from Lanarkshire, calling for the consideration of measures for safeguarding the interests of practitioners who might in the future be called for service with the Forces, and the other from Westminster and Holborn, requesting the Council to consider the advisability of appointing a legal co-ordinating committee in view of the increasing complexity of legislation since the inception of the National Health Service.

A motion by Bradford which was put forward said the mover (Dr. R. H. Sunderland) with a desire to remove misunderstanding and doubts regarding the status of the British Medical Guild, asked the meeting to express the opinion that the only organization which could protect the interests of the general practitioner was one holding the certificate of the Registrar of Friendly Societies. Questions were raised as to whether such a motion was in order, on the ground that two months' notice had not been given, and that if the motion were implemented it would involve rescinding the decision reached at the Special Representative Meeting concerning the setting up of the British Medical Guild. The Chairman ruled it out of order.

PRIVATE PRACTICE

The Chairman of the Private Practice Committee, Dr. I. D. Grant, gave a summary of the several matters dealt with under this heading which appear in the Annual Report of Council, and said that notwithstanding the large section of business taken over by the General Medical Services Committee it was remarkable how many questions remained within the domain of his committee.

Allowances to Medical Witnesses

Dr. H. F. Hiscocks (South-east Essex), in view of the issue by the Home Secretary of new regulations amending the maximum allowances payable to medical witnesses giving evidence in criminal cases, considered that regulations under which maximum allowances were quoted, but not minimum, led to inequalities in remuneration and were unsatisfactory. He asked the Council to approach the Home Office with a view to a fixed scale of fees being laid down. After giving an instance of what had occurred to a medical witness in his Division, he said that they should demand the rectification of a state of affairs in which professional witnesses could be treated in an arbitrary fashion.

Dr. J. A. Gorsky (Westminster and Holborn) desired to strengthen the South-east Essex motion by adding: "This meeting also views with grave disquiet the action of the Home Secretary in instructing clerks of courts not to pay professional witnesses' fees to whole-time medical officers in hospitals and other health services." The Private Practice Committee had appointed three representatives to go to the Home Office to make representations on this subject. A request that such a deputation should be received was made four or five months ago, and they had not had the courtesy of a reply.

The motion, with the Westminster and Holborn addition, was carried.

The Doctor's Car

On the motion of Dr. J. M. Alston (City) the meeting expressed the view that the sign "Doctor" on motor-cars was now unnecessary and undesirable. Dr. R. Forbes (Hendon) moved to compliment the Council on the design of a car badge prepared in response to the resolution of last year and to restate the view that the badge should be made available forthwith to members of the Association. The purpose of the badge was to enable doctors to make themselves known to the police in a yellow-band area and unofficially to secure a certain amount of priority of treatment.

Dr. D. S. Saklatvala (West Bromwich and Smethwick) hoped that if the present meeting restated anything it would be that any badge was unnecessary and undesirable. Dr. J. B. W. Rowe (Harrow) said that if the badge were made available it would stop the sort of thing he saw the other day—a car with the word "Doctor" on the wind-screen, the port side, and the rear window.

Mr. A. Lawrence Abel (Marylebone) held that there should be something distinctive about a doctor's car. England was almost the only country where there was no indication whatever, except for that overdone word "Doctor." In most countries the registration board of the doctor's car was preceded or followed by the letters "M.D."

The Hendon motion was adopted.

Dr. H. H. Goodman (Newcastle-upon-Tyne) moved: "That this meeting is not satisfied that the profession receives a sufficient measure of priority in the delivery of new cars." The profession should insist on a return to some priority. Any doctor now using a pre-war car should be eligible for immediate supply of a new one.

Dr. Grant said he made no pretence that the car position was satisfactory, but it was not nearly so bad as Dr. Goodman would have them believe. In January of this year the position was so bad that the Association finally got the car manufacturers to agree to what was called a hard core of doctors' cars which really required replacement. The number of "hard core" cases submitted by the Association to the manufacturers was 3,290. The manufacturers took the matter up with the local agents, and as a result of their investigations they cut out 457 of these cases as not being justified. Since January 2,086 cars had actually been delivered, and they had an assurance that within a very short time the remaining 25% would be allocated to the profession. A debt of gratitude in this respect was owing to Dr. Potter, the Assistant Secretary, and his staff. Everything possible was being done.

Dr. P. C. McKinlay (East Yorkshire) moved as an amendment: "That the strongest possible pressure be applied by B.M.A. Headquarters to the appropriate Government Departments to obtain release of cars for doctors instead of the method of persuasion through motor-trade channels." Cars essential for the National Health Service were the responsibility of the Ministry of Health, and it was for the Minister to put pressure on the appropriate Government Department. It was a blow to the prestige of the B.M.A. if members had to turn to other organizations to help them.

Dr. Grant said that the action suggested by this amendment had already been taken.

A representative said that the only way a fellow-doctor had been able to get his car was by being fined at Bow Street because his car was not fit to be on the road.

The East Yorkshire amendment was carried, with the addition of the words: "and instructs the Council to take positive action forthwith to remedy this situation."

Fees

Mr. H. W. Harvey (Marylebone) moved to call the attention of the British Red Cross Society, the St. John Ambulance Association, and the Home Office to the resolution passed at the last Annual Representative Meeting concerning fees for first-aid lectures and examinations (a minimum of one and a half guineas for each lecture, with mileage). This was in view of what was stated in the Annual Report of Council (para. 85). Dr. Grant said he understood that in the great majority of cases this was being carried out. If information was received of cases in which it was not being done action would be taken.

The Marylebone motion was referred to the Council.

Worcester and Bromsgrove desired that when a recruiting board was held in the evening the fee payable should be increased by one-quarter. The representative said that boards were held in the evening to avoid loss of working time to the recruit. Why not compensate the overworked doctor? Dr. Grant said it was not possible to get Territorial recruits for examination in the day-time. It would be difficult, having asked for this work, now to demand a higher fee. The cases were not many. It was agreed to pass to the next business.

Dr. Mona MacNaughton (Newcastle-upon-Tyne) drew attention to the inadequacy of the rate of salary offered to medical students of approved schools in view of the nature and amount of work entailed. She applied various criteria to enforce her argument that this work was underpaid. Among other points, the children were difficult, and it was not suitable for them to attend at the surgery.

Dr. Grant said he was very much in sympathy with regard to the capitation fee in this instance, but with regard to the time spent in the school, this had been estimated for a school of 100 pupils at about one hour per week, for which the doctor received a salary of £75 a year. If information were forthcoming that the doctor had spent much more time than this it would be a good case for more remuneration, but for the coming year the present scale of fees might very well be accepted as a temporary measure.

The motion was referred to Council.

Reports to Insurance Companies

Dr. J. C. Arthur (Gateshead) asked the meeting to reaffirm a resolution it passed in 1937 concerning payment for reports to insurance companies furnished after the death of patients who had been accepted for insurance without medical examination. This resolution affirmed that in such circumstances the certificate should be obtained direct from the medical practitioner of the deceased, that it should not be furnished without the previous consent of the nearest available competent relative, and that a fee of not less than half a guinea should be paid by the insurance company for such certificate. This was amended in 1939 by a resolution calling for the discontinuance of the practice of giving "duration" certificates to insurance companies, or to the relatives at the request of such companies, relating to the health of their patients before death, and asking that practitioners refuse to issue certificates in all such cases.

The motion was accepted by the Chairman of the Committee, *and approved by the meeting.*

Routine Examination of Nurses

Dr. E. C. Dawson (Derby) moved to instruct the Council to press for the payment of fees to practitioners engaged in the routine medical examination of nurses. He said that this had nothing to do with the treatment of nurses in illness. Before the Act the honorary medical staff of the hospital examined these nurses periodically, never expecting remuneration, but taking it as part of their job, but under the Act it was thought that they should receive remuneration. Fees were paid for lectures to nurses, and there should be a fee for examinations of the kind mentioned in this motion. There was also the general-practitioner angle. General practitioners in their surgeries had applications for examination from young girls who were proposing to become nurses. They were in some cases in difficulty as to the sort of examination required, and were rather embarrassed about asking these girls for fees.

Dr. W. Jope (Council) said that at a meeting with the Ministry of Health a few weeks ago it was stated that arrangements had been made for the payment of fees to general practitioners for the examination of nurses to be employed under Regional Hospital Boards, and also of nurses changing from the area of one board to another. He believed the fee was one guinea.

The Derby motion was accepted.

Dr. J. C. McMaster (West Somerset) moved to ask the Council to represent to the appropriate bodies the need for raising the fee of one guinea now recommended for the examination of candidates for appointments under the Regional Boards and

Local Executive Councils, and of half a guinea for emigration, to the same level as that of examinations for life assurance—namely, one and a half guineas.

Dr. Grant said that so far as the emigration fee was concerned the Private Practice Committee would be in entire agreement with the motion. With regard to the other part of the motion he asked that it should not be passed. The examination was not in any way commensurate with a life assurance examination, and the fee of one guinea was not inadequate.

The motion was referred to Council.

OCCUPATIONAL HEALTH

Ethical Rules for Industrial Medical Officers

Dr. J. A. L. Vaughan Jones, chairman of the Occupational Health Committee, moved for approval the revised statement of the duties of and ethical rules for industrial medical officers, which appeared as an appendix to the Annual Report (*Supplement*, April 2) He said it had been widely felt that these rules, first formulated in 1937, were in need of examination. He paid a tribute to the considerable assistance which his committee had received from the Ethical Committee, under the chairmanship of Dr. J. G. Thwaites. The duties of occupational medical officers had been extended under the modern conception of health, with its greater emphasis on preventive work. No fundamental change had been made in the rules, but the rearrangement was advantageous.

The revised statement was approved.

Comprehensive Occupational Health Service

Dr. Vaughan Jones further moved the adoption of the report on "A Comprehensive Occupational Health Service" which appeared as an appendix to the Supplementary Report of Council (*Supplement*, May 21). In doing so he said that this subject was not thought to be urgent until last year, when it became a priority question. The need for a national occupational health service had long been recognized by the Association and other important bodies. With the nationalization of industries following the coming of the Government into power in 1945, a mushroom growth and incoordinated development of industrial medical services had taken place. This piecemeal development was extremely wasteful of medical and nursing personnel. Occupational health owed a considerable debt to the initiative of private enterprise in the industrial field. The greatest need was in the small factories. There was obvious need for the closest relationship between the National Health Service and the occupational health services. The Prime Minister had announced in the House of Commons on June 1 that the Government had recently been considering the relationship between the National Health Service and the various health services provided in industry which made a call on medical man-power. The endeavour was to secure that the country's limited medical resources were used to the best advantage. The Prime Minister had appointed a committee to advise the Government on this matter, and it was very satisfactory that two of their members, Dr. Jope and Dr. Talbot Rogers, were on that high-level committee. ("Hear, hear.")

There was a definite tendency on the part of some people, Dr. Vaughan Jones continued, to consider the development of the occupational health service as a whole-time salaried service. This idea must be countered at the earliest possible opportunity. General practitioners suitably trained acting in a part-time capacity must play a major part in the development of this service. The assistance of all branches of the profession would be required, but the bulk of the work must and would be done by general practitioners. Therefore it was considered essential that an announcement should be made now. There was no suggestion that this service could become a nation-wide one on an appointed day.

Dr. W. N. Leak (Mid-Cheshire) drew attention to the paragraph in the Annual Report which was headed "Prescribing by Industrial Medical Officers." He said that under the new Act conditions were changing. A practice was developing in certain parts of the country whereby patients were asked by their own doctor to go to the factory and get treatment. The changing circumstances of industrial life and the pressure on doctors' surgeries had brought about new ethical and social problems. In some areas this kind of thing had reached such proportions that it had become a real industrial issue. The Council should consider the conditions which were growing up.

Dr. Vaughan Jones said he would accept this as a reference to Council. The matter had already been referred to the General Medical Services Committee, and they had had the benefit of the opinion of that committee in relation to it.

The report was adopted.

NURSING

Dr. Mary Esslemont (chairman of the Committee on Nursing) presented this portion of the Reports of Council. She outlined what had taken place in Parliament since the report was published. The Nurses Bill had passed through the Committee and Report stages in the House of Lords, and efforts had been made to secure amendments in the direction which the Council thought appropriate, and further amendments would be sought in the Committee stage in the House of Commons. She concluded by expressing the thanks of the Committee to Dr. Macrae, Deputy Secretary, for all his help in connexion with the work.

Dr. C. F. Mayne (Plymouth) asked that the Committee on Nursing should take up the question of certain anomalies. He referred in particular to the striking contrast between the salaries paid to highly trained nurses of all types and the clerical establishment of hospitals. A senior sister in his own hospital received £250, plus £120 emoluments, subject to income tax; a junior £180 and £120 respectively, a senior staff nurse £150 and £100, and an assistant nurse £200 inclusive of emoluments. On the other hand, a shorthand typist received £380, an appointments clerk £380, and a junior clerk—really an office boy—£160 as a starting salary.

Dr. Esslemont said she would bring these facts to the notice of her committee.

"BRITISH MEDICAL JOURNAL"

Dr. O. C. Carter (chairman of the Journal Committee) said he had a very satisfactory statement to make with regard to the *Journal*. The circulation had steadily increased owing to the continued rise in the membership of the Association, but also to the increased circulation among non-members. This circulation among non-members stood at the present moment at about 10,000 copies a week. During this last week the record number of 68,000 copies of the *Journal* were posted. During the last 12 months a quarter of a million more copies had been published than during the year before. In addition the *Journal* had increased in size. In fact, in this last year a complete set of *Journals* had contained 800 more pages than in 1947. This great increase had thrown a tremendous strain on the printing capacity by the flat-bed process. The service received had been first class, but the *Journal* had outgrown that method of printing, and it had been decided to revert to printing by rotary press. It was important that quality of production should not be sacrificed to speed. With regard to the contents of the *Journal*, every shade of opinion was expressed. The original articles published continued to be of a very high order. "Any Questions?" was still a very popular feature, and questions were received from every part of the world.

The quarterly journals maintained their high academic standard, but the cost of printing and other services had risen rapidly, and the Council was now finding it necessary to increase the subscription to the quarterly journals—a subscription rate which had remained unchanged since 1926. He submitted the report with confidence. Between the covers of the *Journal* was all that was best in British medicine, and by means of the *Journal* the prestige of the British Medical Association had been maintained and enhanced.

A Popular Health Journal

The report under "British Medical Journal" having been adopted, Dr. Carter went on to move that the Association undertake the publication of a popular health journal, the date for its inception to be determined by the Council in the light of the financial position of the Association then obtaining. He

said that a monthly journal was intended, containing some 64 pages and cover, and fully illustrated. It was felt that this would be practical public relations of the first order. It would give the profession an opportunity of giving public advice on healthy living in its broadest aspect. The Committee had had the advice of two editors of popular publications. It might be asked why an ordinary publishing house had not taken it up. The difficulty was the medical staff. Such a publication was considered to be a job for a medical organization with lay help rather than for a lay organization with medical help. The Committee was confident that the Association could successfully produce a first-rate journal which would be of enormous value not only to the Association but to the whole profession and the public at large.

In reply to a question as to whether they could be assured that such a journal would be kept completely free from medical politics, Dr. Carter said, "Quite definitely, yes."

A Voice: Why?

Dr. Carter: Politics would completely destroy the value of such a journal.

The motion approving the publication of the new journal was carried.

Apathy in the Profession

Dr. A. W. Gardner (Brighton) moved a resolution "viewing with profound regret the apparent apathy in the profession" and instructing the Council to use the editorials of the *British Medical Journal* as much as possible to rouse members of the profession to realize their responsibilities in the outcome of the present conflict. He said it seemed to his Division that more use should be made of the *Journal* to stimulate members of the profession and to dispel apathy. More stimulating articles should be written, and in plain English. This would help the Divisions considerably.

Dr. C. P. Wallace (Guildford) moved as an amendment that the Council be requested to confer with the Editor and the Journal Committee with a view to making the *Journal* more easily readable and therefore more effective as an organ of medico-political opinion. The *Journal*, he considered, was in a large degree responsible for the apathy at the periphery. Too often the scientific articles which appeared were more suitable for specialist journals, and others were produced by intellectual snobs. With regard to the *Supplement*, he urged that it be produced in a more popular form, even at a cost to the Association. He could not agree to the Brighton proposal to instruct the Editor. The Editor, in his view, was comparable to a judge on the bench or a bishop in his diocese. He was in a most privileged position, and it was most reassuring to have heard Sir Lionel Whitby the previous evening say that he had been impressed by the integrity of the Editor. He himself would abhor any suggestion that the Editor should be told to put this or that in next week. An editor would be right to resent such dictation. If they were not satisfied with him they should tell him so, discharge him, and compensate him adequately. But he did urge that an effort should be made to publish the *Journal*, and particularly the *Supplement*, in a more popular form.

Dr. R. G. Gordon (Council) hoped the Representative Body would not countenance any coercion of the Editor. The Editor had done extraordinarily well. (Applause.) Why should the *Journal* be blamed because a certain number of practitioners did not take the trouble to see whether it was interesting or not? In actual fact he was quite convinced that although some 10 or 15 years ago it might have been true that a number of copies were left unopened, this no longer held good. To-day the correspondence columns and the response to "Any Questions?" showed that a very lively interest was taken in everything published in the *Journal*. But Dr. Carter would not mind him saying that the Council through the Journal Committee was constantly examining the situation and trying to make the *Journal* more acceptable to all parts of the profession. A balance had to be kept, and he thought it was being kept so far as the paper situation would allow.

Dr. Carter said it was the fact that in every walk of life there was considerable apathy nowadays, and it was unlikely that the apathy throughout the country would not find some expression in the medical profession. But he did not believe this had anything to do with the make-up of the *Journal*. It was necessary to cater for every type of reader. Next autumn it was hoped to return to a popular pre-war feature, "Treatment in General Practice." The *Journal* would be made more attractive as time went on, with a larger type face and other improvements. The Editor was responsible for all that went in the *Journal* with the exception of material which he was instructed by the Council to publish. As for stimulus, he thought there had been nothing more stimulating than the reports which appeared in the *Supplement* under the heading "The Secretary Reports." It was impossible for a committee to dictate to the *Journal*, but with regard to all medico-political articles the Editor was in close consultation with the Secretary. There was the closest co-operation between the medico-political and the editorial side. (Applause.)

It was moved and immediately agreed to proceed to the next business.

FINANCE

Mr. A. M. A. Moore (Treasurer) presented the financial statement. He referred to the serious loss which the Association had sustained in the passing of Dr. Bone. The Finance Committee in particular mourned a very distinguished figure. Last year was one of heavy expenditure, and for the first time in 30 years there was a deficit on the year's work. This deficit was anticipated from the approximate calculations of the previous year. A large proportion of the additional expenditure could be attributed to the Association's campaign prior to the introduction of the Act. Further deficits must be expected unless the income from subscriptions was increased. The assets as represented by the Association building and its contents had been written down on a generous scale. He drew attention to the amount spent on capitation grants, regional offices, and other matters of local organization—namely £32,295—and to the central meeting expenses—£20,836. He mentioned these items in order that the Representative Body might be fully aware of the need for increased income.

Increase of Membership Subscription

The Treasurer moved the adoption of a recommendation of Council that as from Jan. 1 next the membership subscription rates (except for members of not less than 40 years' standing, those retired from practice with not less than 10 years' membership, and members resident outside Great Britain and Northern Ireland) be increased. The proposed increase in the ordinary subscription is from three guineas to four guineas; that for other categories is set out in the Annual Report of Council (para. 116).

He added that from what he had said already it would be quite apparent that the time had arrived when the Association must increase its income. If the membership was maintained—and he personally had no doubt on that point—it was estimated that this increase in subscription would bring in an added income of between £30,000 and £35,000.

An amendment by Cardiff that the subscription of medical officers in the Public Health Service who received no income-tax allowances in respect thereof should remain as at present was referred to Council.

Dr. C. Watney Roe (Chelsea and Fulham) opposed the projected increase to four guineas. The estimated deficit for 1949 if the subscription was not increased was only £10,000, but an increase of one guinea in the ordinary subscription would bring in another £60,000.

The Treasurer pointed out that the assumption that the increase was equivalent to an extra guinea for every member was quite erroneous. The increase would be between £30,000 and £35,000. He added that the subscription to the Association had been three guineas for the last 26 years. Compared with similar bodies in the Dominions, it was still a very low subscription.

The recommendation of Council to raise the subscription rates in the manner set out was carried by a very large majority.

A Welsh representative pointed out the very small amount down to the Welsh Committee as compared with the Scottish

and Northern Irish Committees. Mr Moore mentioned that £10,000 had been allocated to Wales for the purchase of a Welsh House.

The business under "Finance" was approved.

Further Business

At this point the Chairman said that there was great pressure on the time of the meeting, which must be concluded by a certain hour. He begged those who brought forward motions not to make speeches unless the motions were opposed.

Dr. J. G. Thwaites, chairman of the Central Ethical Committee, in bringing forward the report under "Medical Ethics," referred to the impact of the National Health Service and the increased influence of lay administrative bodies as affecting medical ethics. It had been necessary to take action in several cases successfully on questionaries which medical men in the Service were expected to fill up and which involved a breach of professional secrecy. The high ethical standard of the profession had been well maintained. He closed with a tribute to his predecessor, Dr. N. E. Waterfield, in the chair of the committee.

A motion by Kensington and Hammersmith asking that the pamphlet on medical ethics be issued not only to newly qualified medical practitioners but also to all overseas practitioners who had arrived in this country during the last 10 years was accepted.

Recommendations of Council concerning mortuary accommodation and pathological facilities and also concerning mobile laboratories were approved. These were amended versions of the paragraphs on these subjects which had appeared in the previous Annual Report of Council.

Dr. R. G. Gordon (Council) formally moved the reports under "Nutrition" and under "Science." With regard to the latter he said it was unfortunate that it always came late on the agenda, and its uncontroversial character kept it in the background; but it represented some highly important work. The chief duty of the Science Committee was the allocation of prizes. A very high standard of entry had been reached this year.

Major-General Sir Percy Tomlinson (Council) brought forward the report under "Armed Forces" and mentioned the comprehensive character of the Association's Armed Forces Committee, which now represented all aspects of the Services.

The reports under "Public Relations," "Scotland," and "Wales" were moved formally. Dr. R. P. Liston, chairman of the Films Committee, moved the report under "Medical Films," and spoke of the "farce" of the procedure whereby motions were taken in this hurried manner. The Chairman (Dr. Gregg) took strong exception to the word "farce." Dr. Liston, however, continued to make his objection. The same thing, he said, occurred every year, and it was a reflection on the platform that so many important motions should have to be dealt with at the end of the meeting in this summary manner.

The reports under "International Relations" and under "Medical Benevolence" were similarly taken, and this concluded the Annual and Supplementary Reports of Council.

A motion by Torquay was accepted by the Chairman of Council—

That in order that the Association should become a potent instrument in obtaining satisfaction, the Council should bend all its energies in the coming year to arming the Association with the necessary power to enforce their demands.

Thank You

Dr. J. C. McMaster (West Somerset) moved:

That this meeting desires to express to the Chairman and members of Council and its officers their congratulations and thanks for the excellent work which has been undertaken, as evidenced by the Annual Report of Council, and their continued confidence in the Council.

This was carried unanimously. A further motion by Dr. D. L. S. Johnston (Halifax and Todmorden) expressed the thanks of the meeting to Dr. Gregg for his able chairmanship, and this was carried by the representatives rising in their places and applauding. Dr. Gregg made a suitable acknowledgment. He said he had tried to do his best to get through an immense amount of work in a limited time, and if he had offended any or been guilty of wrongful tactics or omissions he apologized.

The meeting closed at 12.30 p.m.

ADJOURNED ANNUAL GENERAL MEETING

President's Address

The Adjourned Annual General Meeting was held in the Royal Hall, Harrogate, on the evening of June 28, with Dr. C. W. Curtis Bain in the chair. The hall was filled with a distinguished assembly, many wearing academic gowns. The Mayor and Mayoress of Harrogate were among those present.

The Chairman of Council first introduced to the President the following delegates from kindred associations: Major-General G. B. Denit and Lieutenant-Colonel J. W. Regan (American Medical Association), Professors Demuth and Feilinger (Austrian Medical Association), Dr. Edna Guest (Canadian Medical Association), Dr. A. Clausager-Madsen and Dr. V. A. Fenger (Danish Medical Association), Dr. P. Moran and Dr. P. T. O'Farrell (Medical Association of Eire), Dr. Olafur Bjarnason (Icelandic Medical Association), Dr. E. Rabau and Dr. H. Steinitz (Medical Association of Israel), Dr. Eilert Eilertsen (Norwegian Medical Association), Dr. E. H. Cluver, Dr. J. Harvey Pirie, and Dr. A. H. Tonkin (Medical Association of South Africa), and Docent Stig Berseus (Swedish Medical Association).

The distinguished foreign guests next introduced were: Professor Hilding Bergstrand (Stockholm), Dr. Robert A. Hingson (Baltimore), Dr. J. Lövset (Bergen), Dr. Winifred Pitkin (New York). Professor Stefanopoulo (Paris), and Dr. Leon Unger (Chicago).

Representatives and delegates from Overseas Branches of the B.M.A. included: Dr. F. W. Hanford (Northern Rhodesia), Dr. D. E. Thompson (Tanganyika), Dr. D. R. Belletty (Assam), Dr. W. Balendra, Dr. S. L. Navaratnam, and Professor C. C. de Silva (Ceylon), Dr. R. E. Anderson, Dr. R. B. MacGregor, Professor J. K. Monro, and Dr. A. A. Sandosham (Malaya), Dr. J. Coen, Mr. N. McAlister Gregg, and Mr. G. C. Halliday (New South Wales), Dr. J. Lloyd Simmonds (Queensland), Dr. R. A. Burston, Dr. L. Ll. Davey, Dr. W. M. Irwin, Dr. H. M. Jay, and Dr. Peter W. Verco (South Australia), Mr. G. E. Foreman and Dr. G. T. James (Victoria), and Mr. Henry H. Hill (Western Australia), Dr. Salvatore Debono (Malta), Dr. P. J. Fogarty, Dr. Owen Johnston, and Mr. Norman C. Speight (New Zealand), and Dr. C. J. Austin (Fiji).

The Gold Medal

The Chairman of Council said that the next item on the programme was a sad one. It was a posthumous presentation to Mr. Alan Bone, F.R.C.S., of the Gold Medal of the Association which was awarded to his father, the late Dr. J. W. Bone. Dr. J. W. Bone was a very faithful servant of the Association, whose loss they all mourned. The medal was accompanied by a testimonial setting out Dr. Bone's record of work. The testimonial concluded:

In you the Council admires a colleague of high capacity and wide learning, the promise of whose early academic brilliance has been amply fulfilled in the years of maturity. It salutes in you a man greatly gifted in the handling of practical affairs, persuasive in debate, and skilled in the art of negotiation, independent of mind yet ever attentive to opposing arguments and ever responsive to the claims of comradeship. In sincere appreciation of your outstanding achievements, and gratefully recognizing that the many and exacting public duties which you have undertaken have been fulfilled with a completely unselfish and single-minded devotion to the welfare of the Association and of the whole profession, the Council delights to confer upon you the highest distinction within its gift.

The Association prizes were next presented: the Middlemore Prize to Dr. A. A. Douglas (Birmingham) for his essay on "The Value of Orthoptics in the Treatment of Squint"; the Nathaniel Bishop Harman Prize to Dr. F. Hampson (Grimsby) for his essay on "Endometrial Biopsy: Studies on the Normal and Pathological Histology of the Human Endometrium."

The Dawson Williams Prizes were then presented to Dr. J. C. Spence (Newcastle-upon-Tyne) for his research into diseases of children, and to Professor Alan Moncrieff (London) for his work in the field of child health. Nurses' prizes were also presented, the first to Miss G. Kenneth (Malvern) and the second to Miss E. A. B. Davis (London), these in a competition for State-registered nurses not working in hospital. Miss Jean Cumming (Middlesex Hospital) won the prize for student nurses. Prizes were presented to the following medical students for their essays on "The Value of Observation in the Training of the Medical Student."

Mr. L. H. Berman (Edinburgh), Mr. H. J. Bland (Bristol), Mr. H. J. Dawson (Leeds), Mr. M. H. Gough (St. Thomas's), Mr. J. S. Kennedy (Glasgow), Miss Mary C. Shaw (Bristol), Mr. M. H. Sheard (Manchester), Mr. G. T. Smerdon (Oxford), and Miss S. M. Taubner (Royal Free).

Lady Whitby invested Mrs. Bain with the President's Lady's Badge. In so doing she said how much she had enjoyed her term of office and the friendliness with which she had been everywhere received. Mrs. Bain said that she felt she was accepting this decoration on behalf of doctors' wives all over the country, who had to run their houses, bring up their families, and often act as unofficial assistants.

The President then delivered his Presidential Address on "Man and the Machine," which was published in the opening pages of the *Journal* last week.

Finally Dr. E. A. Gregg, Chairman of the Representative Body, proposed a vote of thanks to the President for an address of great weight and scientific interest. They were all indebted to Dr. Bain for having prepared and delivered an address so carefully constructed and documented. The vote of thanks was heartily accorded, and the formal proceedings terminated.

The meeting was followed by a reception given by the President and Mrs. Bain. The numbers attending were so large that the guests had to be divided. Some 600 proceeded to the Royal Baths, and an equal or greater number remained in the Royal Hall. Dr. and Mrs. Bain received their guests at each place in turn. Light refreshments and music were provided.

PROCEEDINGS OF COUNCIL

Monday, June 27

The last meeting of the old Council was held in the Council Room of the Municipal Offices, Harrogate, on Monday, June 27, with Dr. H. Guy Dain in the chair.

The congratulations of the Council were extended to those members of the Association upon whom honours had recently been conferred by H.M. the King. The Chairman said that they would note with special pleasure the knighthood conferred upon Mr. H. S. Souttar, a former Chairman of Council, the C.B.E. for Professor Picken, a prominent former member, and the O.B.E. for Dr. N. E. Waterfield, a present member.

A letter was read from the Medical Secretary of the Medical Association of Eire thanking the Association for its great kindness in arranging to lend that body the sum of £10,000 over a term of twenty years, and without any interest, subject to certain conditions as to repayment.

On the motion of Dr. Pridham, the Council approved, on the request of a large number of members of the Association, the formation of a Tuberculosis and Diseases of the Chest Group.

Association Prizes

Dr. R. G. Gordon, for the Science Committee, brought forward recommendations for the awards of the Association prizes. These included the Nathaniel Bishop Harman Prizes, the prizes for medical students, the Association prizes for nurses, and the various scholarships. A variation had been made in the Association prizes for medical students, for which a total of 53 essays had been received, and the Committee recommended, the Council agreeing, that a total of ten national prizes, each consisting of a certificate and a cheque for £25, should be awarded.

Public Health

Dr. James Fenton, chairman of the Public Health Committee, presented a report on various outstanding matters. These included a statement prepared by the Joint Subcommittee (of the Central Consultants and Specialists, General Medical Services, and Public Health Committees) on the report of the Working Party on Midwives. The Association supported many of the recommendations of the Working Party, but felt that those concerned should recognize that there was no acute crisis in the midwifery profession. Tribute was paid in the comments to the continuous efforts which had been made during the last twenty years by the Central Midwives Board, the College of Midwives, individual tutors, and matrons, to develop the profession, and it was considered that the best results in the future would be achieved by fostering these existing agencies.

A report on action taken was presented by Dr. Wand for the General Medical Services Committee. It concerned the position on remuneration, inflation of doctors' lists, and other matters.

The Central Consultants and Specialists Committee reported that the Minister of Health had decided to appoint a departmental committee to advise how the statutory registration of opticians could best be effected and what qualifications should be required as a condition of registration. The Council decided that the Faculty of Ophthalmologists, the Royal College of Physicians, and the Royal College of Surgeons should be invited to co-operate in setting up a joint committee to prepare a statement of the profession's requirements in this respect, and to collect evidence in support thereof for submission to the departmental committee. The Council appointed three representatives to the Joint Committee.

The Council had before it a confidential report by Mr. St. J. D. Buxton on his visit to Greece as a B.M.A. lecturer, discussing in particular a number of problems concerned with orthopaedic surgery which he had encountered during his stay in that country. Mr. Buxton was heartily thanked for a valuable report, the recommendations of which would be forwarded to the appropriate quarters.

Wednesday, June 29

The first meeting of the new Council was held in the Municipal Offices, Harrogate, on June 29.

Election of Chairman

After discussion Dr. E. A. Gregg was unanimously elected Chairman of Council. He said he could not think that any service he had been able to render to the Association had merited this honour, but he would do his best; and he knew that his shortcomings would be forgiven. He had a real desire to do the right thing and to be fair and just in all his actions.

The Retiring Chairman

The new chairman then asked the Council to pay its tribute to his predecessor. They had always been fortunate in the British Medical Association in those who had occupied its important offices, but they had had no one who in steadfast devotion to the Association's interests and the interests of the profession had spent himself more unselfishly than Dr. Dain. The speaker was able to recall within his own experience practically the entire Association career of the retiring chairman. He remembered him in the old days when he was an ordinary member of the Insurance Acts Committee. From then onwards he had been the unswerving, patient, persistent worker on behalf of his profession that they knew so well. As chairman of the Insurance Acts Committee, of the Conference of Local Medical and Panel Committees, of the Representative Body, and, finally, of the Council, always he had been the same Dain, unassuming, pretending to no gifts of oratory, but offering an example which was outstanding and unforgettable. "We have never had anyone like Dain before—I say that without the smallest fear of contradiction. We have had all sorts of brilliant people who had done wonderful work, and we have appreciated them, but Dr. Dain stands by himself.

On your behalf I offer him the very sincere thanks of this Council and of the Association for the magnificent work he has done on our behalf."

The members of Council rose in their places and applauded.

Dr. Dain, in response, said he could imagine no greater opportunity for the development of character than to have served the Association. Any qualities which he might possess at the moment had been developed over the years in his contacts with members of the various committees and of the Council. He was unable to imagine anything he could have enjoyed better, and if anybody had had any fun out of it he was sure it had come to him. He had always held that responsibility was the salt of life, and this had been his during the last five years in good measure. He had been very happy in the work. The atmosphere in the Council and in the Association generally had been delightful; the friends he had made had been many, and he would not have missed a minute of the experience. In latter years the Association had given him the opportunity of extending his travels and his friendships overseas, and it had been a highly interesting and exciting experience. He had now felt that it was proper and right that he should bring his term of office to an end, but he hoped to be able to continue as a member of Council for a while and to serve on a number of committees in whose work he was specially interested.

New Members

Twelve new members of Council were welcomed.

Dr. Wand, who was *ex officio* a member of Council by virtue of his chairmanship of the General Medical Services Committee and was also one of the eight elected by the Representative Body, said he would prefer to have it in the records that he was a member of Council by the votes of his colleagues rather than by virtue of his office, and it was agreed that some words should be found to denote this.

Dr. Dain read a letter he had received from Dr. J. A. Ireland, no longer a member of Council, expressing appreciation of the kindness and consideration he had received at his hands during the last six years.

Committees

The Council proceeded to the election of its own members on the Standing Committees and to the reappointment of such Special Committees as had not discharged their reference. The composition of the International Relations Committee was widened to include the chairman of the Board of Management of the Empire Medical Bureau and representatives of the British Council and of the British Medical Students' Association.

It was intimated that the Central Medical War Committee had been asked to continue until the end of 1949, but it was expected that it would then cease to exist and that the Government would form a small committee of its own to carry on the work.

N.H.S. Conciliation Machinery

The Council then unanimously agreed to the passing of a resolution expressing surprise and regret at the Government's decision to withhold from the medical profession the right to have disputes referred to arbitration:

This decision (the resolution continued) is a violation of assurances and carries with it constitutional implications of the gravest character, involving open discrimination against professional workers by denying to many of them the rights freely accorded to others engaged in national services.

Autonomous Bodies within the Association

Following upon the Bournemouth resolution in the Representative Meeting asking the Council to appoint a special committee to consider and report on the situation created by the formation of autonomous bodies within the Association and their relationship to the Representative Body, the Council appointed a special committee of 15 members, including the Chairman of Council, Sir Lionel Whitby, and Dr. Dain, its terms of reference being the words of the Bournemouth motion, and it was expected that it would bring in an interim report in October.

Other Business

The report of a Joint Committee of the B.M.A. and the National Veterinary Medical Association was before the Council, but it was stated that the veterinary body was still considering a number of the points, and general approval was accordingly deferred.

A report of a Joint Committee of the B.M.A. and the Pharmaceutical Society was submitted, and its three recommendations were approved as follows:

That it is undesirable that a doctor and a pharmacist should practise from the same premises unless each has a separate address and there are separate means of access to the two addresses.

That it is undesirable that a doctor should have a financial interest in directing his patients to a particular chemist when there are other chemists in the area.

That in order to preserve the principle of free choice and to avoid abuse it is undesirable that a doctor should recommend a particular chemist, or a chemist a particular doctor, unless he is specifically asked to do so by the patient.

It was proposed that the Ethical Committee should be consulted on the ethical problems involved.

Dr. J. A. L. Vaughan Jones, on behalf of the Occupational Health Committee, brought forward a recommendation for the approval as an interim arrangement of certain rates of remuneration for whole-time and part-time medical officers of the National Coal Board, and this was agreed to.

The Secretary reported that he had been in informal discussion with whole-time medical Civil Servants with a view to placing the Association in the right relationship to them on the matter of negotiation on remuneration. Subject to the approval of the Council, it had been agreed that the remuneration of whole-time Civil Service medical officers in relation to the Spens Committee reports should be handled by a committee consisting of three members of the B.M.A. Council, three of the Institute of Professional Civil Servants, and three of the Ministry of Health Medical Staff Association.

The Council agreed to this course and appointed Dr. C. Metcalfe Brown, Dr. James Fenton, and Dr. Dain as its representatives on the proposed committee.

Dr. Vaughan Jones gave notice that at the next meeting of Council he would ask it to consider a motion that chairmen of committees presenting reports at the Annual Representative Meeting be given adequate time for the presentation of their reports to the Representative Body.

OVERSEAS CONFERENCE

The Overseas Conference in connexion with the Annual Meeting was held in the Council Chamber, Harrogate, on Wednesday, June 29. Dr. J. B. Wrathall Rowe, retiring member of Council for the West Indian Branches, took the chair, and the new Chairman of Council, Dr. E. A. Gregg, was present.

Survey of the Colonial Services

Dr. E. GREY TURNER, Assistant Secretary, in charge of the work of the Colonies and Dependencies Committee, gave a brief report. He said that at Headquarters they did their best always to bear in mind the problems of the overseas member. The Colonial Office had agreed that the terms of service in the Colonial Medical Service must be broadly equivalent to those in the National Health Service at home. An attempt had been made to work out a colonial interpretation of Spens. Many special factors had to be brought into such a calculation—taxation, pension arrangements, housing, and a factor which was usually called expatriation. The people in the Colonies were in some ways better off and in other ways worse off than in this country, but the Colonial Office had rejected the suggestion that the various factors might be held to cancel one another out, holding that the figures should be worked out, plus or minus, and the Spens salaries adjusted in that way.

Taxation in the Colonies was very much lower than in this country, but this disparity might lessen, as there was a prospect

of colonial income tax going up. Moreover, the colonial medical officer, in return for such income tax as he paid, did not get the advantage of many of the social services and general amenities which the tax provided, although it might be said that in this country also the social services were not much used by doctors. Pension schemes varied from Colony to Colony, but were substantially more generous than the N.H.S. superannuation scheme. The colonial medical officer was also provided with a house, though the housing might not always be very satisfactory.

The difficult factor of expatriation had also to be taken into account. The colonial medical officer, recruited in the United Kingdom, spent his time working at a great distance from home, and was put to heavy expense in such matters as the education of his children. Cost of living was a difficult factor to assess. Then the colonial officer was separated from his family to some extent. How was that hardship to be allowed for? He had to admit that he had utterly failed to convince anyone that life in the Colonies was substantially at a disadvantage as compared with life in the United Kingdom. He had pointed to the lack of cultural facilities, but he had been told that this was offset by the facilities for sports and games in the Colonies. A figure had to be attached to all these factors and the Spens figure adjusted accordingly. A further point was that the Spens reports were based on U.K. doctors working in the U.K., and it was questionable whether they had any relevance to, say, locally recruited African doctors working in Africa. The utmost should be done to obtain for the locally recruited members the most favourable terms possible, and they must rely on the Branches to negotiate those terms and inform headquarters.

Other matters were being discussed. One of them was recruitment procedure. Sometimes senior appointments were left vacant for long periods. The impression was that those concerned did their best, and that delay was sometimes unavoidable. Other matters were the burden of non-medical work, the thorny problem of private practice, and finally—a matter which he mentioned with a little diffidence—the fact that in some parts of the Colonial Medical Service the spirit of those who worked in it appeared to be unduly depressed. The service did not seem to be as self-confident or as proud of itself as it should be.

A Quick Look Round

Dr. Grey Turner then gave a quick impression of the state of the Branches in the colonial Empire. The Fiji Branch had revived its activities, and was holding four meetings a year. The Hong Kong and China Branch was full of activity and optimistic about the future. The Malayan Branch was large and flourishing. The Indian Branches were in a state of suspended animation at the moment. The Indian and Pakistan Medical Associations had recently been formed, and discussions with the Indian Association were already taking place with a view to affiliation, and it was hoped soon to be in touch with Pakistan. A difficulty was the Indian licentiates. If full affiliation were granted to the body of licentiates in India, difficulty might be encountered among Indian members, of whom there were many, in East Africa. Ceylon was engaged in converting itself into an incorporated Branch, and in future would bear the alternative title "Ceylon Medical Association." The Association at home would continue to take a slightly more remote but none the less warm interest in its affairs.

The Tanganyika Branch went into a period of quiescence during the war, but its activities were now extending. The other Branches in East and Central Africa were flourishing. The Egyptian Branch was quiet at the moment but was remaining in being, and Sudan was keen and active. Almost 100% of the doctors on the "Rock" were members of the Gibraltar Branch. In Malta the Ministry of Health had prepared a health scheme, and the Branch had set up a joint negotiating committee with the Camera Medica. There were a good many members in Transjordan, and he hoped that the Palestine Branch might be transformed into a Transjordan Branch. It was hoped to revive the Mesopotamian Branch, possibly under another name, and to include the many doctors on the Persian Gulf. Many of the West Indian Branches were not very active, though some of them had recently been revived. Sierra Leone Branch was the only one on the West Coast of Africa. The Association had 114 members in Nigeria, and 65 on the Gold Coast, but no Branch, which was a great pity. At Headquarters they were, in the words with which a predecessor of his used to sign his letters, "Always at your service within the limits of our power."

Dr. SANDIFORD, director of the Empire Medical Advisory Bureau, said a few words on the personal service to visiting overseas members which the Bureau performed. Up to the end of May there had been 776 inquiries of the Bureau, and 433 visitors had paid over 800 visits. Most of the visitors came for postgraduate instruction, and the Bureau had a synopsis of the regulations for the various diplomas. The Bureau was able also to help in finding accommodation.

General Discussion

Some of the overseas representatives present made brief observations. Dr. R. E. ANDERSON (Malaya) said that income tax had just been instituted in Malaya, and no doubt would get larger. The housing position in Malaya, perhaps owing to the influx of officers to the new departments, had become acute, and in a number of instances there was a waiting-list. Officers in Malaya tended to keep their children there because of the enormous cost of education in England. Petrol in Malaya cost 3s. 5d. a gallon, and was rationed. Dr. R. B. MACGREGOR (Malaya) considered that the possible hardship of the early age of retirement in the Colonial service should be stressed. It was impossible to generalize on the cost of living in the Colonies. In Malaya the price of many commodities was three times the pre-war cost.

Dr. D. E. THOMPSON (Tanganyika) spoke of the isolation of district medical officers, and the lack of contact with specialists and pathologists. These officers were entirely on their own and had to deal with every emergency that came along. The population expected a comprehensive medical service, and looked to the district medical officer to provide it and made it known in the chamber of commerce or legislative council if he did not. His colleagues in Tanganyika would not be satisfied with the partial restoration of private practice which had been foreshadowed in the Philippson report. They took the view that they would like an adequate salary so that they were free from financial worries, and if that was not possible they would press for the complete restoration of all the sources of income, including private practice, which they had lost.

Dr. J. SCOTT BROWN (Uganda) resented the idea that the colonial officers were geographically and climatically in a happy situation. Save for a small part of Kenya, the colonial empire was no place whatsoever to which people would care to retire. He had rather detected in Dr. Grey Turner's speech a tendency to put forward the Colonial Office point of view instead of the point of view which colonial officers had been bringing home to the Association during the last year or two. Dr. F. W. HANDFORD (Northern Rhodesia) spoke of the cost of living in the Colonies, and particularly the high cost of basic foodstuffs in his country, where there were no food subsidies. Mr. J. M. FITTON (Mauritius) was amazed at the work which the Association was doing for its overseas members. He referred to the lack of materials for hospital medical services abroad. Dr. C. J. AUSTIN (Fiji) mentioned a visit which he had recently paid to Jamaica, where he found what he considered to be a very flourishing Branch.

Dr. CHARLES HILL (Secretary) gave a brief account of the British Commonwealth Medical Conference at Saskatoon, which was attended by Dr. Dain and himself and by representatives of the Dominions. It was an extraordinarily valuable conference, particularly in its examination of the relations between the profession and the State. The next conference was to be held in Brisbane in 1950, and it was hoped that the conference the following year would be in South Africa. He added that clearly the visit of Dr. Grey Turner to the East Africa Branches this year had been greatly appreciated. Advice would be offered to the Colonies and Dependencies Committee that its secretary or some member of the committee or both should pay an annual visit to some of the overseas Branches. If that

was done it should be possible within a relatively short time for all the Branches to be visited.

Other Business

It was reported that a medical officer in the R.A.F. had submitted a suggestion that the Government should establish a boarding school in the United Kingdom for the children of officers in the Armed Forces and in the Colonial Service. An alternative suggestion was that the Government should reserve places in State-aided local authority boarding schools for the children of such officers. The Armed Forces Committee of the Association and the Colonies and Dependencies Committee had asked that the matter be considered by those attending the Overseas Conference. The chairman suggested that representatives on their return should seek the opinion of the other members in their area and write to the Secretary of the Colonies and Dependencies Committee on the subject.

Dr. GREY TURNER made a brief statement on the control of overseas advertisements in the *British Medical Journal*. Overseas Branches occasionally requested that advertisements be refused, without giving adequate reasons. The Committee would work out a policy whereby this control might be more efficient and expeditious. Advertisements could only be refused if they cut across the definite policy of the Association or broke a negotiated agreement. It did not help if an overseas branch secretary returned an advertisement with the remark, "We think this is a little below what it should be." The policy when fully worked out would be communicated to Branches.

Dr. WRATHALL ROWE closed the meeting with an expression of the good wishes of the Association at home to the representatives on returning overseas and to their colleagues in their various countries.

ANNUAL DINNER

The Annual Dinner of the Association was held in the Hotel Majestic, Harrogate, on June 30. A company of just over 400 assembled under the chairmanship of the President, Dr. C. W. Curtis Bain. The guests included the Lord Bishop of Ripon, the Mayor of Harrogate, and others who had afforded hospitality and service to the Association in the course of the meeting, as well as a number of oversea delegates and representatives.

Mr. A. DICKSON WRIGHT, in proposing the toast of "The Mayor and Corporation," referred to the abounding hospitality of Harrogate. Everything the town had had been at the disposal of the visitors. Although the profession had been converted into a public utility, it was a great thing to find that it still had some life left in it and was able to hold its annual conference with the same good spirit of comradeship it had always exhibited.

The MAYOR, Mrs. Fisher, J.P., spoke of the pride she felt in welcoming the Association to Harrogate as one of the first acts of her year of office. If Harrogate had come up to expectations the local people were well rewarded. Another source of pride for Harrogate was the election of Dr. Curtis Bain as President, and she wished him a successful year of office.

"The British Medical Association"

The LORD BISHOP OF RIPON (Dr. Chase) said that he had had a good deal of contact with doctors. In the first war he was a padre, and for the first two and a half years he was attached to one of the hospitals in this country and shared the doctors' mess. Later he was at Cambridge at a college where one of the Fellows was professor of pathology, afterwards the master, and he always brought in the examiners to dine with them in hall. He heard their tales at dinner, and this made him more inclined to propose the health of the patients than that of the doctors.

The Bishop went on to say that he had read a certain amount of what the Association had been talking about during the week, though he could not pretend that he knew very much about the B.M.A., but the previous week he was in London and there at lunch he met a doctor whom he found to be interested in one part of the work of the Association and who spoke of it in highly complimentary terms. This was its work in welcoming doctors and research students from overseas, making them feel at home during their visit to this country and putting them in touch with the right people. His doctor friend bore testimony to the enormous value of that work, and the Bishop wanted to endorse his tribute.

Dr. E. A. GREGG made his first public speech as Chairman of Council in responding to this toast. He began with a reference to his predecessor, Dr. Dain, and the regret they all felt that he should have come to the end of his term of office and relinquished the chair which he had filled with great distinction through such a long and difficult period. He then added for his own part an expression of thanks to all who had contributed so splendidly to their comfort during this visit to Harrogate. It had turned out to be one of the best and happiest meetings the Association had ever known. One of the memories of it he would carry away was of a gracious little lady presenting the Association with a banner in the name of the Mayor and Corporation of Harrogate. That banner would be hung in Tavistock Square. In course of time its colours would dim a little, and other banners would be added there, but for those who had attended the Harrogate meeting it would always continue to evoke the most happy memories.

The Bishop had said that he did not know very much about the B.M.A. What was the B.M.A.? It was the organized representation of the medical profession in this country. It contained within its ranks over 80% of all the doctors. When it spoke it had a right to claim that it was expressing the views of the profession. It spoke as a democratic organization. Some might think, reading the proceedings of the last week, that the voice was a little confused, but for all that the general view of the majority was finally expressed in the form of an easily understood resolution which was rightly taken as the expression of the views of the doctors of this country.

The British Medical Association sought to gather together the views of doctors generally, and to express professional opinion on all subjects. But by far the greater part of the work was concerned with the advancement of scientific knowledge and with assisting doctors in their relations with one another. The Association had asked that the great National Health Service should be introduced by stages; it said it was too big a thing to be introduced all at once, and it had been proved right. The whole scheme did not hatch out of the brain of Whitehall; it had been borrowed from the profession itself, which had been working on the subject for thirty years at least. It had asked Government after Government to devise a scheme of medical care for the people of this country. But this request fell on deaf ears, until a few years ago "when they woke up and took over our stuff, adding to it ingredients which made it less good." He thanked the company for the way in which the toast had been received.

"The Guests"

Dr. T. V. PEARCE, chairman of the Harrogate Division, proposed the health of the guests. He referred in particular to the guests from overseas. There were guests present that evening from China, Israel, Poland, France, Holland, Denmark, Sweden, Iceland, and the United States. The republic of Ireland was represented, as well as all the Dominions—Canada, Australia, South Africa, New Zealand, India, Pakistan, and Ceylon. The Branches represented stretched from A to Z—from Assam to Zululand.

Dr. N. MCALISTER GREGG, *M.C.*, made the first of two responses to the toast. New South Wales, he said, his part of the world, still considered itself as belonging to the British Empire and thought of England as home. He found changes in England, but there was still the same spontaneous and abundant hospitality. He acclaimed the work of the Empire Medical Advisory Bureau.

Major-General G. B. DENIT, M.D., of the American Medical Association, brought greetings and best wishes from that body and from the Surgeon-General of the U.S. Army. The medical professions of their two great countries had always worked together, in peace and war, and the tremendous advances of medicine during the last two decades might be said to represent

their combined efforts. Great Britain had launched on a programme of socialized medicine, while in America they had only talked about it, or, more properly, talked against it. But in America they were watching the British experiment with profound interest, and its success or failure would determine to a large extent their own course.

"The President"

The final toast, that of "The President," was proposed by Dr. W. RUSSELL BRAIN. He spoke of Dr. Bain out of a friendship of more than thirty years, and told one or two stories of his Oxford student career. Subsequently he established himself in practice in Harrogate, where he had built up a great reputation. In his presidential office he would guard those essential values of medicine which were their particular responsibility in the present situation.

The PRESIDENT contented himself in his reply with making grateful reference to his Harrogate colleagues who, while he himself had been more or less a figurehead, had worked over a long preparatory period to make the meeting a success. Praise was due in the first place to Dr. D. D. Payne, the Hon. Local General Secretary, and to Dr. J. V. Wilson, the Hon. Local Science Secretary, who had carried through one of the revolutions they had made at Harrogate—the institution of a four-day scientific programme. Dr. T. G. Reah had been responsible for the entertainments and excursions, Dr. T. A. Best for the dinners and luncheons. Dr. T. V. Pearce and Mrs. Pearce, M.D., must have made many friends in their arrangements for the hospitality of overseas visitors; they had corresponded personally, and sometimes at length, with everyone of the overseas guests. The Ladies Committee had been admirably guided by Mrs. D. D. Payne. There were many others who should be mentioned in connexion with transport arrangements, premises, sport, the museum, and to all of them their thanks were due. The scientific programme was entirely in the hands of the presidents and other officers of the sections, and he hoped that the programme provided had been to the taste of the visitors.

THE REPRESENTATIVES' DINNER

The representatives attending the Annual Meeting at Harrogate, with their ladies, dined together at the Grand Hotel on Monday evening, June 27, under the chairmanship of Dr. E. A. Gregg. The proceedings were shortened owing to the fact that the Annual General Meeting of the Association was to follow immediately, and, as usual, the only toast to which there were speeches was the health of the Chairman of the Representative Body. This was in the hands of Dr. D. M. Hughes, of South-west Wales, who spoke of the charming and patient way in which Dr. Gregg had handled a difficult meeting. Although occasionally he had been stern, he had always been very fair and very straight. However troublesome representatives might become, however unjust their criticisms of the Association, however unlearned they might show themselves in the rules of procedure, the Chairman was invariably fatherly and kind. He had carried through his duties with a fortitude and a skill which they from the body of the hall had sincerely admired. Dr. Hughes also accorded a gracious welcome to Miss Gregg.

The toast was accorded musical honours.

Dr. Gregg said that he had awaited the judgment of his colleagues in the Representative Body with some trepidation, because as time diminished and the pressure of business in the meeting increased, he had had occasionally to be ruthless. But events showed that he need not have feared; and why indeed should he fear in any gathering of the British Medical Association? The members were invariably generous in their appraisement of any ability one put into one's job and in overlooking the many faults of which he himself was conscious. He must be forgiven if he had in the Chair done some things which he ought not to have done, and had omitted to do some things which he ought. His aim had been to get the business through. These annual meetings were a constant struggle to get a quart into a pint pot, to get through in three or four days an amount of work which ought to take twice as long if only the time were at their disposal. He thanked those concerned especially with the last set of amendments in Monday's proceedings—those dealing with the Association war memorial. He had taken unpardonable liberties with those amendments, doing all sorts of things which were unconstitutional, but it was the only way to get the thing completed. The representatives, like the generous people they were, had helped him through it. He spoke in conclusion of the pleasure and satisfaction of working for the Association.

MEDICAL MISSIONARY BREAKFAST

A small company accepted the invitation of the Medical Prayer Union to a "Missionary Breakfast" at Harrogate Hydro on July 1. The President of the Association, Dr. C. W. Curtis Bain, was in the chair, and introduced Dr. R. C. Cochrane, honorary director of the Leprosy Campaign for the Government of Madras, and formerly principal of the Christian Medical College, Vellore.

Dr. Cochrane spoke of the recent political advance of India, where in two years as much had been accomplished as in the previous fifty. He said that missionaries, like others, had to accept the fact that countries such as India were subscribing to an ideology under which it was the State's job to carry out the work of healing and were organizing hospitals along those lines. Although State medicine in the full sense of the term did not yet prevail in India, the Government was largely responsible for medical work. Some of them as missionaries twenty or thirty years ago, aware of the tremendous need, tended to get into a panic because they measured it only against their own poor resources; but they were primarily out there, not to meet need, but to show how need should be met, and to challenge the Government so that it might see that the right approach to the work of healing was a spiritual one.

They had to bring their contribution as physicians and surgeons into the set-up which they found in these missionary countries. Dr. Cochrane spoke of Gandhi, with whom he had conversations with the object of interesting him in the campaign against leprosy. Gandhi told him that he was already interested. He was the greatest leader, said Dr. Cochrane, that India had ever produced, and, moreover, a leader influenced greatly by Christian teaching. He trusted that Gandhi's influence would permeate the new India. In that new India, with its awareness of modern medicine as of other things, medical missionaries had an even greater task and responsibility than in the past.

RELIGIOUS SERVICES

Priests and Physicians

The official religious service in connexion with the Harrogate Meeting was held at St. Peter's on Tuesday afternoon, June 28 when the preacher was His Grace the Archbishop of York. Members robed in the Royal Hall, and, preceded by the professional staff and by the banner presented by the Mayor of Harrogate, walked to the Church. The Mayor and members of the Corporation also attended. The service, which was broadcast in the Northern Programme, was conducted by the Vicar (the Rev. R. H. Baines); the Bishop of Ripon (Right Rev. G. A. Chase, D.D.) was present. The lessons were read by Dr. H. Guy Dain and Dr. C. W. Curtis Bain, the new President. The two hymns were both by medical authors: "Lord of all being," by Oliver Wendell Holmes, and "Praise the Lord! ye heavens, adore Him," by Edward Ostler, an early nineteenth-century surgeon. The words of the anthem, "From Thee all skill and science flow," were by Charles Kingsley, set to music by Dr. Thalben-Ball. A collection for medical charities was taken.

Dr. Garbett, in his sermon, said that the Church had learned to welcome the great advances made in medicine and surgery. It saw in these advances the continuance, under new conditions, and with new methods, of its own healing work. There were various ways in which the Church could help the doctor. The properly trained and spiritually minded parish priest by his ministrations could co-operate with the physician in the

restoration of the sick. Many diseases which were at one time regarded as physical were now known to have their roots in the depths of the mind. Sometimes it was plain that an illness was due to a spiritual cause—depression, persistent and enervating anxiety, the darkness of melancholia, what our fathers would describe as sin. There were diseases for which the help of the priest was required. Advice and treatment given by the doctor needed sometimes to be supplemented by the gospel of faith and forgiveness. Sometimes the priest and the doctor working together could do what neither could do separately.

The Church could also join with the doctor in the war against such social evils as bad housing and malnutrition. Much had been done to reduce malnutrition, but he feared that many mothers of families still suffered from under-feeding. Much had also been done since the war to build new houses, but overcrowding was still an appalling evil. Here the Church could join with the medical profession in exposing these problems.

There was a third way in which the Church could help in the work of healing. It taught the value of the individual, and demanded that every man, woman, and child should be treated with respect and reverence as of value in the sight of God. There was a tendency to-day to lump individuals together and group them under the label of "the common man." There was no such thing as a common man. The medical profession had inherited a noble tradition of treating their patients as individuals with special needs and characteristics. In the medical profession the family doctor had always been held in affection and respect. It might not be so easy to continue in the future, with increasing specialism, the tradition whereby the doctor gave to each patient full individual attention. It would be tempting to make a swift diagnosis and set the patient in a groove in which all were treated in much the same way. Against this the overworked priest and the overworked doctor must be ever on their guard. The fundamental difference between the patient in a totalitarian and in a democratic State was that in the former his value to the State was the first consideration, and if he was feeble, crippled, and unable to do useful work he was thrown on the scrap-heap, whereas in the democratic State each was, or should be, treated according to his special needs. The medical profession, said the Archbishop in conclusion, was passing through a critical and anxious time, but he trusted that out of it would emerge ultimately great blessings for the community.

Roman Catholic Service

Roman Catholic members of the Association, some of them in academic gowns, attended the celebration of Benediction at St. Robert's Church, Harrogate, in the afternoon of June 30, when an address was given by the Bishop of Leeds (Rt. Rev. H. J. Poskitt, D.D.).

The work of medicine, said the Bishop, always ended in apparent failure. No matter how good the doctor or how marvellous the treatment, sooner or later the patient died. It seemed always as if doctors were trying to do the impossible, to confer immortality upon the mortal, to defy the Word of God, which declared, "Dust thou art, and unto dust shalt thou return." Not only was there apparent conflict in the sphere of life and death but in that of pain and suffering. The Christian faith taught that man was destined by the Fall to suffer in this world, and yet the whole work of doctors was to fight such suffering and to banish pain. But all this supposed conflict between religion and medicine was superficial. The work of medicine, so far from contravening the law of God, was fulfilling it in redeeming humanity and exalting the value of human life.

The Bishop went on to remind Catholic doctors that many of the great moral problems were in the field of medicine—contraception, artificial insemination, sterilization of the unfit, euthanasia. It was most important that doctors should be properly instructed in handling ethics to meet these materialistic theories on their own ground. Catholic doctors should make it their business to join the Guild of St. Luke, where they would breathe the Catholic atmosphere and would be taught Catholic principles as applied to the practice of medicine.

OPENING OF EXHIBITION

The Exhibition of Surgical Instruments and Appliances, Drugs, Foods, and Books was installed in the Sun Pavilion at Harrogate. It was opened on the first day of the meeting by the President, Dr. C. W. Curtis Bain.

In his first public speech as President, Dr. Bain said that one of the preoccupations of those who had arranged that meeting at Harrogate was to find a place where the exhibitors could display their products to advantage. The medical profession realized to the full the value of the contribution which the manufacturing firms represented in the Exhibition were making to medicine. One had only to think of the products of modern times—insulin, liver extracts, the vitamins, thiouracil, mercury diuretics, and, not least, the sulphonamides and penicillin—to realize what had been achieved in research and production. Now they were awaiting a product which it was hoped would revolutionize the treatment of rheumatoid arthritis.

There had been a change in the medical profession since the meeting a year ago. In fact, the manufacturers represented in the Exhibition seemed to be one of the few examples of free enterprise remaining. He wished the exhibitors a successful week, and declared the Exhibition open.

The Chairman of Council, in thanking the President, spoke of the ever-increasing interest of the preparations which were introduced for the treatment of disease. The last session of the Representative Meeting was put back a little in order that representatives might look round the Exhibition.

THE POPULAR LECTURE

"HEALTH AND HAPPINESS": BY DR. CHARLES HILL

The closing event of the Harrogate Meeting was the Popular Lecture, which was delivered in the Royal Hall on July 1 to an audience of about 1,300. The lecturer was Dr. Charles Hill, and the chair was taken by the President of the Association, Dr. C. W. Curtis Bain, who was accompanied by the principal officers of the meeting. The Mayor of Harrogate was also on the platform.

Dr. Hill said that his chosen subject, "Health and Happiness," presented so vast a canvas that it was impossible to do more than touch on some of its aspects and make some random reflections. Health and happiness were essentially matters for the individual. Health was difficult to define and measure. Mortality figures, the incidence of infectious diseases, the extent of incapacity were statistically demonstrable, and there had been various health surveys, but even when the last figure had been worked out the picture remained incomplete. It was necessary to beware alike of the politicians who painted improved health in rosy colours with the implication that they themselves were responsible for the improvement, and those who drew a mournful and distressful picture with the object of inflicting their particular nostrums on the people.

What was health? It was more than mere freedom from disease and discomfort. It had been said that it was essentially unawareness of what was going on inside. Mark Twain defined digestive health as, "Eating your food and remaining in blissful ignorance of its melancholy fate in the department below." But what was health in the ideal sense? Was it not something over and above mere mechanical fitness or mere freedom from organic disease? Was there not some "plus" which represented the difference between ordinary existence and the buoyant lively existence of the exuberantly healthy?

There were those who found their happiness not in health but in the lack of it—who "enjoyed bad health." "There are people who do not hesitate even in this beautiful town of yours to throw their varicose veins in your face." But another form of inverted happiness was an excessive interest in positive health—the muscle boy who judged health by the measurement of his biceps, who proudly took his 12 short breaths before the open window in the morning. There were the people who went to near and distant spas in order to absorb such sustaining fluids as might be there available. There was an attitude of mind which was obsessed with health. On the

other hand, the genuinely healthy attitude of mind was not one preoccupied with disease nor with health itself but a sane and sensible outlook based on a knowledge of how the human body worked, with a determination to observe the simple rules of healthy conduct which led to the maintenance and development of health.

The Components of Happiness

From this brief survey of health Dr. Charles Hill turned to a consideration of the problem of happiness. He refused to consider happiness in terms of endocrine glands or of psychotherapy. Happiness was difficult without health, but complete and buoyant health was impossible without happiness. Perhaps to define happiness, to condition it too closely, was to endanger it. Happiness did not depend on surroundings. "More happiness may be experienced by a man playing darts in a pub than by a young hussy sipping cocktails in a high-class hotel." A great deal of happiness in this world came from making other people happy. One of the tragedies of recent developments, however commendable such developments might be on some of their merits, was that they tended to narrow the opportunities of service to others. Too many people were trying to squeeze happiness out of life instead of putting something into it.

An often forgotten source of happiness was a little praise. This was not sufficiently realized in the home. The healthy emotional development of a child needed as part of the building-up process a certain amount of self-confidence and a sense of his worth-whileness which praise could give. In earlier and less sophisticated days there was a warmth and richness of happiness which we were in danger of losing to-day. There was happiness, too, in being treated as an individual and not as a number. There was happiness in being able to live one's life in one's own sweet way. There was some danger of losing one's self in the organization of one's life. Happiness was a matter of simple, unexpected pleasures—"a job to do, something to enthuse about, something to get on with, something that makes you work—for the time has come when we must preach and recognize the essential virtues of work. The mother with the large family has not time to be unhappy. We are pressing for more and more leisure and shorter and shorter hours before we have mastered the art of using our leisure."

Was security necessary for happiness? In some measure, yes. Certainly a sense of security was necessary to the happiness of children. But it was possible that we might be heading for a new problem—the problem of excessive security. Had civilization increased our health and happiness? Well, man had certainly learned the erect posture, but the orthopaedic surgeons were very busy. We drew food from every continent in the world, but digestive troubles increased year by year. Nicotine, alcohol, caffeine—we relied on them more and more in a sort of vague belief that there lay the road to happiness, but we knew that that belief was vain. We knew full well between ourselves that to base our search for happiness on stimulants and narcotics was to lose the quest. We were in fact pursuing something elusive if we set out to search for happiness along such roads. He agreed that many who preached the simple life did not practise it, and told the story of the surgeon who, after giving certain advice, was reminded that he did not follow it himself. His reply was that he was a signpost, "and you do not expect a signpost to travel to where it points."

A Return to the Greek Ideal

Health was largely not a matter of hospitals, doctors, and nurses, but of good housing, good food, and a right attitude of mind, a sensible observance of the rules of living, facilities for education and recreation, and, not least, the individual's assumption of his own responsibilities in this field. A return was needed to the Greek ideal of balance, moderation, and the restoration of the family as the natural unit of society. In listing some of the things which made for happiness he had omitted the satisfaction which came from happiness in marriage. Men were apt to treat the subject with a cynical laugh, but let them be unashamed in this matter and admit that marriage had been the source of richest satisfaction and happiness. A cynical Restoration poet declared that courtship is to marriage what a witty prologue is to a dull play. Well, let them face the dullness, the humdrum of matrimony, and find there a greater satisfaction than in all the glittering externals of this life of ours.

That view might be old-fashioned, reminiscent of lace curtains and aspidistras. But this country could do with a little more of the old-fashioned loyalties and co-operations and, within the family circle, could find greater delight in the simple, the small, the ordinary.

In closing, Dr. Hill pleaded for a more intelligent attitude towards the achievements of medicine. The notion that health was mainly a matter of the medicine-bottle must be exploded. There had been enormous progress in the treatment of disease by drugs during the last 16 or 17 years. Medicine was equipped as never before to fight and to treat a number of infections. But it still remained true that there were far too many people who swallowed a bottle of medicine and expected some magic to be wrought. There was still a secret faith in the unorthodox and the dramatic. Perhaps it was well not to deny people their dreams, not to deride the idea that the eating of crusts was the effective way of producing ringlets in the hair. Let them beware of the invention of new symptoms and the building up of new diseases for which some expensive quack remedy was immediately forthcoming.

THE PATHOLOGICAL MUSEUM

The Pathological Museum, which was opened by Professor M. J. Stewart, attracted a steady flow of visitors throughout the week. The whole exhibit had been admirably planned and laid out by the museum committee, with Dr. Georgiana Bonser as chairman and Drs. T. V. Sutherland and J. V. Wilson as joint secretaries. What made the museum particularly attractive to a diversity of medical visitors was the variety and scope of the exhibits. Pathology itself was well represented by a fine collection of specimens from Professor Stewart illustrating ulcers, cancers, and polyps of the stomach, and cicatricial deformity with pouch formation of the first part of the duodenum following chronic duodenal ulceration. Professor C. Polson (Leeds) supplied ophthalmological specimens of melanomata, gliomata, and various non-malignant conditions. Specimens illustrating bone and joint diseases were contributed by Dr. D. H. Collins (Leeds). An assorted collection of interesting and rare exhibits came from Professors R. J. V. Pulvertaft (London), J. Magnus (London), and T. F. Hewer and his colleagues (Bristol). Dr. J. N. Wilson showed specimens directing attention to the frequency of neoplastic disease in infancy and childhood. Dr. J. W. Burn (Grimsby) showed some of his unique collection of specimens of congenital heart deformities, and there was a most attractive exhibition of medical paintings done by Mary D. Brown for Mr. Allison, of the General Infirmary, Leeds, depicting cancers and peptic ulcers of the stomach and oesophagus. In the same room were photographs from Drs. A. Macpherson and G. M. Findlay (London) of phagedaenic ulcers, noma, and gingivitis treated effectively with penicillin.

An exhibit which excited much comment was a series of electron photomicrographs and x-ray diffraction photographs from Professor W. T. Astbury (Department of Biomolecular Structure, Leeds) showing the detailed structure of muscle and related tissues. The cross-striated collagen fibrils in the connective tissue of human skin and the hill and valley ridging of the epidermis were wonderful to behold. There were other excellent anatomical exhibits in this section, while in another room Professor A. C. Frazer (Birmingham) had a series of diagrams illustrating the partition hypothesis of fat absorption with special reference to the sprue syndrome.

Professor H. E. Shortt (London) had a coloured diagram and microscopical preparations showing the complete cycle, including the exo-erythrocytic stage in the liver of the mammalian malarial parasite, *Plasmodium cynomolgi*, and Professor B. G. Maegraith (Liverpool) demonstrated the pathogenesis of hepatic centrilobular degeneration and necrosis (anoxic syndrome) in the liver lesions in malaria.

An interesting exhibit put up by the Pharmaceutical Society showed methods of sterilizing glassware, oily solutions, suspensions, and powders, etc.; *p*H estimation and sterility tests of solutions for injection; the curarizing effect of decamethonium iodide; and the pharmaceutical application of ultra-sonics.

GOLF COMPETITIONS

The golf competitions at Harrogate attracted a larger entry than usual. As there were three courses available the variety added much to the pleasure of the competitors. The very dry conditions made play on all courses difficult.

Treasurer's Cup.—This was played at Pannal Golf Club and won by Dr. John K. Mackay, of Middlesbrough, with a score of 73 less 1=72 (scratch score being 75) from a field of 29 entrants. The runner up was Dr. L. Hurrich, of Bradford, with 80 less 7=73.

Leinster and Childe Cups.—This competition against bogey was played on the course of the Oakdale Golf Club. The Leinster cup open to all was won by Dr. G. Blair (7), of Middlesbrough, 1 up. The Childe Cup open to those with handicaps of 10 and over was won by Dr. Arwyn Evans (10), of Cardiff, 3 down.

Notts Ladies Challenge Cup.—This was played on the course of the Harrogate Golf Club and unfortunately the entry was small. The winner was Mrs C. R. D. Leeds with a score of 89 less 17=72. The runner up was Dr. M. E. Johnson with a score of 92 less 19=73.

OTHER ENTERTAINMENTS

Visitors to the Annual Meeting at Harrogate were given the choice of many entertainments. Some of these have been described in this issue, but there were many others, more than enough to fill every minute of a crowded week.

While the representatives were debating arbitration some of their ladies, thanks to the kindness of H.R.H. the Princess Royal and the Earl of Harewood, enjoyed a visit to Harewood Park and Gardens. Over the first week-end there were opportunities to admire Rievaulx and Byland Abbeys, Ripon and Fountains Abbey, and to explore the Richmond and Wensleydale countryside. On the Sunday evening there was an operatic concert.

Throughout the week there were tours to Ilkley and Bolton Abbey, Brimham Rocks, Fewston, Burnsall and Appletreewick, Aldborough and Ripley Castle, Spofforth Castle and Plompton Rocks. York attracted many visitors and so did Templenewsam. The excursion to Haworth and the Brontë country was popular and so were visits to Knaresborough Market, Listers Mills, and other centres. Everywhere the organization ran smoothly, and hospitality maintained the Yorkshire tradition.

For the less energetic there were film shows every day and notably "The Medical Motion Picture" which was prepared originally for the centenary meeting of the American Medical Association. There was a cocktail party for the Press and a sherry party arranged by the Medical Women's Federation.

Two functions were attended by many overseas delegates and their ladies. At the British Council's reception on Tuesday evening the guests were welcomed by Sir Gordon Gordon-Taylor, and on the following day a cocktail party was given by the Empire Medical Advisory Bureau.

The Glasgow Graduates had their dinner on Saturday, June 25, and the Irish Graduates' Lunch, which used to be held at annual meetings before the war, was again an enjoyable occasion. After this and other luncheon parties tours of the Royal Baths were popular, and the famous waters were sampled freely.

A great deal of interest was shown in the mobile health unit provided by the Joseph Rowntree Village Trust and on view for two days near the Royal Hall. The ladies found even more to interest them in the mannequin parade which formed a novel part of the Garden Party given by the Harrogate Division on Thursday, June 30.

During the whole meeting there was garden party weather. All the visitors were delighted with Harrogate, and there were few who did not enjoy private hospitality as much as the many more formal entertainments.

HEARD AT HARROGATE

The A.R.M.

The Representative Meeting was the largest since long before the war, and the debates, though scarcely tinged with bitterness (except against the Minister of Health), showed little humorous edge either. By Saturday night fewer than a hundred of the 250 motions and amendments on the agenda had been disposed of. Generally the first morning of the Representative Meeting is given up largely to formal matters, but at Harrogate scarcely were the representatives seated before they were plunged into the big discussion on arbitration and Whitley machinery. If anybody had an idea that the setting up of autonomous committees would ease the burden on the Representative Body, and shift a number of matters on to a conference representing general practitioners in the Service, or one representing consultants, he was disillusioned. The reports of both the General Medical Service and the Central Consultants and Specialists Committees bristled with points which speakers were eager to take up. Yet during the first two days of the meeting there was only one occasion, and that over a relatively minor matter, when there was a close division on a show of hands. Almost everything else was unanimous, or as near unanimous as makes no difference. Once only the voting revealed a majority of two. Someone demanded a recount, and it was put to the meeting whether there should be a recount or not, with the inevitable result that the ayes and noes were again relatively equal. A recount was, however, taken and showed that the majority of two had been halved. The Chairman was assailed with advice as to what he should do in these circumstances—have a card vote, a roll call, a division—but he took the sensible course of proceeding to the next business.

Emperors of Fourth Estate

The Press at Harrogate were accommodated in curtained boxes all around the arena, rather like emperors watching the gladiatorial combat. It is one of the blessings of microphone and amplifier that speeches in large assemblies can be heard equally well in any part of the building, so that there is no longer any need for the reporters to be crowded together at one long table underneath the platform, where they intimidate some speakers and embolden others.

The Section Meetings

It was a new experience for the Sections to gather in comfortable hotel lounges instead of in hard-seated and bare lecture theatres, and to have a break in mid-morning for coffee. The members who attended took full advantage of these amenities, and found that the easy chairs and gilt mirrors and the ornate furniture and tapestries of luxury hotels interfered not at all with their appreciation of angiocardiograms or whatever it might be which was demonstrated on the lantern. The four-day Section meeting was an innovation which seemed to justify itself. In one of the Sections which met on each of the four days the attendance on the last day was the best of all, except for one combined meeting with another Section.

Old Days Back

The Royal Hall at Harrogate, which seats 1,250 people, and stands a good many more, underwent various transformations during Annual Meeting week, and if halls have any personality it must have been rendered giddy by its experiences. For four days it was the forum of medico-political argument, interrupted by a Sunday on which it staged an operatic celebrity concert. On the fourth night it was like a senate house, with gorgeous academic robes and significant ceremonies. On the following night, when the Mayor of Harrogate gave a civic reception to the Association, receiving as many guests as the hall would hold, it was given up to revelry. The arena was cleared for dancing, and those who looked on from the amphitheatre or the galleries probably had as much enjoyment as did the eminent, and some of them venerable, members of the profession gyrating below. But in the corridors afterwards there were tables stretching out apparently to infinity and laden with confectionery. An old member of the Association declared that the old days had really come back again.

STANDING ADVISORY COMMITTEES
CHAIRMEN APPOINTED

The Standing Advisory Committees constituted by the Minister of Health (*Supplement*, Feb. 5, p. 58, and Feb. 12, p. 72) to advise him and the Central Health Services Council on various parts of the National Health Service have elected the following chairmen and vice-chairmen (their home town is given in parentheses):

Medical.—Chairman: Professor Sir Henry Cohen (Liverpool). Vice-chairman: Dr. J. A. Brown (Birmingham).

Dental.—Chairman: Professor R. V. Bradlaw (Newcastle-upon-Tyne). Vice-chairman: Mr. H. T. Roper-Hall (Birmingham).

Pharmaceutical.—Chairman: Alderman W. J. Tristram, M.P.S. (Liverpool). Vice-chairman: Mr. R. H. Henriksen, M.P.S. London).

Nursing.—Chairman: Miss C. H. Alexander, S.R.N. (London). Vice-chairman: Alderman A. F. Bradbeer (Birmingham).

Maternity and Midwifery.—Chairman: Sir William Gilliatt, P.R.C.O.G. (London). Vice-chairman: Mr. A. W. Walker (Cambridge).

Mental Health.—Chairman: Sir Allen Daley (London). Vice-chairman: Dr. W. G. Masefield (Eastbourne).

Tuberculosis.—Chairman: Professor Sir Harry Platt (Manchester). Vice-chairman: Sir Robert Young (London).

Cancer and Radiotherapy.—Chairman: Sir Ernest Rock Carling (London). Vice-chairman: Professor E. Finch (Sheffield).

Ophthalmic.—No permanent chairman has yet been appointed.

The Minister has appointed Miss C. H. Alexander, S.R.N., matron of the London Hospital, to fill a vacancy on the Central Health Services Council caused by the resignation of Miss M. E. G. Milne, S.R.N., on the grounds of ill-health.

MEDICAL AUXILIARY WORKERS
RECRUITMENT AND TRAINING

The Minister of Health and the Secretary of State for Scotland have set up eight committees to review questions of recruitment, training, and qualifications of medical auxiliary workers in the National Health Service. All eight committees are under the chairmanship of Mr. V. Zachary Cope, former President of the Board of Registration of Medical Auxiliaries. Two members on all the committees are Dr. G. A. Clark, Principal Medical Officer, Ministry of Health, and Mr. A. B. Taylor, Assistant Secretary, Department of Health for Scotland. The other members of each committee are:

Almoners.—Dr. F. GRUNDY, Miss M. M. McInnes, Miss M. J. Roxburgh. One vacancy.

Chiropodists.—Mr. ST. J. D. BUXTON, Miss D. Grant Nisbet, Miss C. F. Norrie, Dr. J. A. SCOTT.

Dietitians.—Miss M. C. Broatch, Professor S. J. COWELL, Dr. D. P. CUTHBERTSON, Dr. G. GRAHAM, Miss R. Pybus.

Laboratory Technicians.—Mr. T. C. Dodds, Mr. A. Norman, Dr. G. S. WILSON. Two vacancies.

Occupational Therapists.—Miss M. D. Barr, Miss E. M. Macdonald, Mr. L. W. PLEWES, Dr. T. P. REES.

Physiotherapists.—Mr. J. T. Buchan, Mr. J. H. C. Colson, Dr. J. L. LIVINGSTONE, Miss M. I. V. Mann, Miss M. U. Sharpe, Mr. T. T. STAMM, Dr. W. S. TEGNER.

Radiographers.—Dr. S. COCHRANE SHANKS, Professor G. Stead, Mr. C. Lovell Stiles, Mr. R. White, Professor B. W. WINDEYER.

Speech Therapists.—Dr. E. J. BOOME, Dr. J. B. GAYLOR, Mr. V. E. NEGUS, Dr. C. C. WORSTER-DROUGHT. One vacancy.

The secretary of all the committees is Mr. J. G. Paterson, of the Ministry of Health.

CONSULTANTS ADVISED NOT TO SIGN

The Joint Committee of the Royal Colleges, the Royal Scottish Corporations, and the Central Consultants and Specialists Committee sent the following letter to the Ministry of Health on July 5.

Dear Sir William,

The Joint Committee at its meeting to-day, after considering the views of its constituent bodies, passed the following resolutions:

1. The Joint Committee finds itself unable at present to advise consultants and specialists to enter into permanent contracts on the basis now offered by the Minister.

2. The Joint Committee finds it essential to reopen discussions with the Minister on the following points:

(i) There should be established for consultants and specialists a permanent negotiating machinery, the Minister or the representatives of the profession having the right, in the event of disagreement, within an agreed range of subjects to refer the matter for settlement by arbitration, both parties being bound by the award of the arbitrator.

The agreed range of subjects should include any terms and conditions of service affecting remuneration.

The form of contract should be revised so as to make it clear that the terms and conditions of service offered are those which have been agreed with the profession or determined by arbitration, and not "determined from time to time by the Minister of Health."

(ii) Facilities for private treatment in hospital should be maintained and developed throughout the country for those who desire them.

(iii) Information concerning the remuneration of part-time clinical teachers should be available before the practitioners concerned are called upon to sign permanent contracts.

3. *In the meantime the Joint Committee recommends consultants and specialists not to sign permanent contracts until further advice is tendered by the Joint Committee.*

The Joint Committee desires an interview in order to discuss these resolutions.

Yours sincerely,

(Signed) LIONEL WHITBY,
Chairman of the Joint Committee.

Questions Answered

Three Problems

Q.—*(1) Is a separate fee still payable for a doctor called to a road accident? If so, by what procedure is the fee obtained? I was recently called to an accident involving a motor-car and motor-cycle.*

(2) I have recently been requested to immunize and vaccinate State patients privately. Can a doctor charge for this service if desired by the patient and the material is purchased by the doctor?

(3) I have received numerous requests for the prescribing on Form E.C.10 of various types of contraceptives. In some cases contraception is advisable for medical reasons, and in others desirable for social and economic reasons. Can a doctor order these materials on Form E.C.10?

A.—(1) A separate fee under Section 16 of the Road Traffic Act, 1934, may be claimed when a doctor is called to a road accident. The claim should be made immediately to the injured party's insurance company.

(2) If the patient is a public patient of the doctor concerned no private fee may be claimed in respect of vaccination and immunization.

(3) Discussions are now in progress on the prescribing of contraceptive appliances on Form E.C.10 whether for medical or social reasons. At present these appliances may not be prescribed.

Correspondence

Comparative Incomes

SIR,—The observations by "A.C.E." (*Supplement*, June 18, p. 354) regarding the comparative incomes of medical practitioners, dentists, etc., are most interesting. In view of the present dissatisfaction among medical officers in the local authority medical services regarding salaries, the following table of comparative rates of remuneration of public health medical officers, specialists employed part-time by local authorities, and N.H.I. fees of general practitioners over the past ten years may prove of interest to members of the profession.

	Askwith Memorandum for Assistant Medical Officers	General Practitioners' Capitation Fees	Specialists' Fees for Part-time L.A. Service	
			Consultation	Sessional
1939	£500 - £25 to £700	9s.	£2 2s. 0d.	£2 12s. 6d.
1942	do	9s. 9d. (i.e. + 8%)	do.	do.
1943	do	10s. 6d. (i.e. + 16%)	£2 10s. 4d. (i.e. + 20%)	£3 3s. 0d. (i.e. + 20%)
1946	£650 - £25 to £850 (i.e. + 30%)	15s. 6d. (i.e. + 72%)	do.	do.
1947	£675 - £25 to £875 (i.e. + 35%)	do.	£4 4s. 0d. (i.e. + 100%)	£4 4s. 0d. (i.e. + 60%)
1949	do	Approx. 17s. (i.e. + 88%)	—	—

The percentages given above in respect of assistant medical officers are the increases of the minimum salaries in each range over the 1939 minimum. A person on the maximum salary (£700) in 1939 and now getting £875 p.a. is proportionately worse off, as his increment is only 25% of his 1939 remuneration.

Probably there are few members of the profession outside the public health medical services who are aware that medical practitioners in these services are still paid on a scale originally introduced in 1929, and as recently as 1946 were receiving salaries at the same figure as in 1929 apart from a small war bonus (an increase of only 9% or less).—I am, etc.,

Stafford. H. L. SETTLE.

Hospital Waiting-lists

SIR,—Is it not time that Mr. Bevan realized, or that we made him realize, that his own vindictive regulations are largely responsible for the hospital waiting-lists?

In pre-war days, when accommodation itself was not at the low ebb of the post-war period, the general wards mainly served the "working-class" population. The middle and professional classes did not, as now, compete for admission to these wards, for they had a choice of reasonably priced rooms or cubicles in the hospitals, or a fair range of nursing-home prices.

By Mr. Bevan's regulations the private accommodation in hospitals is now prohibitive. Many London nursing-homes were bombed, and new ones are not likely to arise so long as Mr. Bevan retains the "right" of taking over any going concern of this nature.

Thus at present the entire population is competing for admission to beds formerly mainly reserved for the working classes. In fact, foreign visitors are also allowed to add to the lists and are freely catered for at the taxpayer's expense. But the private British patient—tax-paying and scheme-contributing—obtains no benefits at all, and pays purchase tax on medicines.

These regulations arise at a time of low accommodation, shortage of staff, shortage of visiting and private nurses and of home-helps. It is therefore almost impossible to be ill and adequately nursed at home. Therefore again, the waiting-lists swell.

Cannot the B.M.A. insist:

(1) That in the future any nursing-home or small hospital of private enterprise be un-interfered with?

(2) Some reasonable paying accommodation in hospitals be allowed?

(3) Foreign visitors not accepted in the scheme?

(4) Purchase tax on medicines be reconsidered?

(5) To save taxpayers, some contribution by the recipient be made for wigs, surgical corsets, etc., also for the second or third pair of glasses?

The scheme from the beginning has had many anomalies, many injustices, and many extravagant vote-catching sections. The B.M.A., it appears to me, can only go on trying persistently to stand up for the rights of *all* sections of the population and patch up a singularly ill-thought-out programme.—I am, etc.,

London, W.1. A. BROMAN.

Special Tax

SIR,—The slogan at the time of the introduction of the National Health Service was, "No payment at the time of service." If it was the intention to raise the slogan to the status of a *principle*, which was my impression at the time, subsequent experience has surely proved it wrong. The cost to the Exchequer for the services of the medical profession was accurately forecast. The cost of the services in terms of effort on the part of the profession was completely ignored. How often have we not heard the phrase, "I have come to you, doctor, for such and such, because by so doing it costs me nothing"? The saving of a paltry sum of money for the odd bandage or packet of aspirins *costs* the doctor expenditure of time and effort; but the thoughtless patient assesses it as a pure saving for himself in terms of money.

The bill for the medicines, spectacles, and what not, paid for on a cost-per-item-of-service basis, could not be so accurately forecast. Unlike the item of professional service, its cost is not in sweat and weariness but in terms of pounds, shillings, and pence. I am not concerned to demonstrate the rottenness of the slogan, "No payment at the time of service," elevated to the status of a principle in practice, but I am most concerned to support most strenuously the plea of Dr. Peter H. Keppich (*Supplement*, May 28, p. 300) that any form of contributory payment that may be introduced should not be directed to assessing each item of medical service at either a shilling, a penny, or a pound.

I should be loath to see it assessed at anything in terms of money. Let us take our living in terms of capitation or salary, as you please, for we have to live. But let the item of payment for service at the time of service be directed to the charge of 1s. for each item on a prescription paid directly to the chemist, who is in most instances also a retailer of private prescriptions of his own or proprietary firms. Such a standard charge per item prescribed could be easily collected, would act as a safeguard on the expenditure of public money, and indirectly would relieve the burden on the profession.

I would make only one exception: items to children under school-leaving age should be left free of charge, thus ensuring no neglect of children's ailments.—I am, etc.,

South Molton, Devon. R. A. NASH.

Pay of Service Medical Officers

SIR,—I have read with interest and mixed feelings the letter of "R.A.M.C." in the *Supplement* of April 30 (p. 258), which I received to-day.

I quite agree that the remuneration of medical officers in the permanent Forces is too low and in some cases totally out of proportion to the work that they do. For example, a friend of mine on this overseas station is shore-based and attends the wives and families of the naval and dockyard personnel; and he has estimated that, if he were "outside" as a civilian general practitioner under the N.H.S. scheme, the fees that he would receive from his maternity work alone would be greater than his present rate of pay.

On the other hand the medical services have a higher rate of pay than the executive branch: I, in my second year in the Service, have a higher rate of pay than the executive officer in this ship, who is due for his half-stripe this year and is one year my senior in age. If the B.M.A. Council's proposals were implemented, then it would be grossly unfair to the executive branch if their pay was not proportionately raised.

The theory advanced that medical administrative work should be treated as a specialist appointment, and therefore should

receive specialist emoluments, must amuse the general practitioner working in the N.H.S., with his increased secretarial work, and also the executive officers or adjutants, who have as much, if not more, administrative work but do not get an increased rate of pay. On the other hand, some form of incentive for the doctor with higher degrees to enter or remain in the Services will have to be devised, but I cannot foresee the Lords Commissioners of the Navy or the Army or Air Force Councils permitting a gross disparity of pay between the different branches of their Services, rank for rank.

Does this R.A.M.C. officer consider himself worse off financially than an executive officer of similar rank in his unit? If so, he has just cause for complaint. But if he chooses to remain in the Services he should not start comparing his financial status with that of his colleagues in civilian practice, he should consider the discrepancy in pay of an Army officer with that of those in a similar position in other professions. He may then be thankful he did not choose the Church.—I am, etc.,

SURGEON-LIEUTENANT, R.N.V.R.

Rate of Payment

SIR,—Surely doctors in the underpaid areas are entitled to more support than they seem to be getting from the Association. Headquarters declare that proof is forthcoming that sufficient money has been paid into the Central Pool to allow a capitation fee of 17s. 5d. per annum. Here in Cornwall doctors are being paid at the rate of 15s. 5d. per annum. The difference must be going to someone, but it is difficult to discover to whom. To find oneself less well-off by £200 per annum than doctors in other areas with lists of the same size is a disquieting experience.

Again, the mileage unit in Devon is worth precisely 25% more than the same unit in Cornwall. Why should a doctor in Cornwall receive a cheque for £100 while his colleague "over the water" with the same number of units on his list receives £125?

Are we, in this county, subsidizing inefficiency on the administrative side in our own area or at a higher level?—I am, etc.,

Launceston, Cornwall. DONALD M. O'CONNOR.

*** The Secretary of the Association writes: Basic salaries and inflation of doctors' lists are the two main causes of the lower rate of payment in most areas. For causes of inflation, see "The Secretary Reports" (*Supplement*, June 4, p. 303). Inflation does not necessarily result in underpayment. Its effect is that the properly constituted "pool" has to be spread over many more names than would be the case if doctors' lists were cleared. The General Medical Services Committee has discussed with the Ministry of Health the question of clearing doctors' lists as speedily as possible.

Transport to Hospital

SIR,—Recently a directive has been issued by the local executive council concerning the use of free transport to hospital. It states that a patient may be allowed this service on condition that his illness is of such a degree that he is unable to travel by public transport.

Just as I have to sign false certificates to enable patients to obtain corsets, so I am now forced to order transport, willy-nilly, unless I wish to alienate the patient's feeling for his doctor. How can one possibly judge in every case who shall ride in comfort and who shall fight his way to hospital as best he can? Admittedly, there are a few clear-cut cases, but the vast majority cannot be assessed so easily. Home conditions, difficulty of access to public transport, the awkward hour of appointment—all these factors may be a greater disability to the patient than "the degree of illness." Here again it should not fall to the doctor to stand in judgment.

Quite apart from this problem is the burden placed on the doctor of finding himself deputy unpaid "M.T.O." In my own rural practice I have had frequently to make a visit of 10 miles or more solely to inform the patient when his transport will arrive and to confirm that I have managed to arrange it. Many other examples of these complications can be quoted, such as the occasions when the car has been delayed or fails to materialize. Frantic 'phone calls on my part from a telephone kiosk near one of my branch surgeries are usually in vain, and one is held responsible for all these difficulties, which are bound to arise from the very nature of the scheme. Incidentally, each of my 'phone calls costs a minimum of sixpence, and on one occasion it cost me 3s. 8d. The eightpence had to be borrowed from the patient. One county ambulance centre now require a *special* form to be filled up in every case, but they offer to pay postage, so one should not grumble too much.

Another aspect is the appalling number of cars which have to be ordered for patients attending the out-patient physiotherapy department of a hospital. In many instances the doctor has not ordered the treatment himself, and in some cases the whole set-up is the happy hunting-ground of the conversion hysteric, who prescribes for himself different forms of electrical treatment with increasing enthusiasm for his newfound outlet.

If we have decided that this country can afford a "free" health service, and that the patients are to be provided with hospital cars, then let the patient himself contact the ambulance control centre and explain his circumstances to the officer concerned. As long as certain basic requirements are fulfilled, then transport should be granted.—I am, etc.,

JOHN ESKELL.

St. Briavels, Glos.

Association Notices

PHYSICAL MEDICINE GROUP

A meeting of the Physical Medicine Group will be held at B.M.A. House on Friday, July 15, 1949, at 2 p.m. The main business will be to receive the report of the Group Committee and to discuss any other matters of interest to members.

After the general meeting, at approximately 3 p.m., Dr. W. S. Tegner, chairman of the Group Committee, will address the meeting on his recent visit to America for the International Congress for Rheumatic Diseases. Any non-members of the Group who wish to attend to hear this address will be welcome.

CHARLES HILL,
Secretary.

THE ASSOCIATION OF CERTAIN OVARIAN CELLS WITH ENDOMETRIAL CANCER*

BY

WILFRED SHAW, M.D., F.R.C.S., F.R.C.O.G.

AND

BURJOR DASTUR, M.D.Bombay, M.R.C.O.G.

(From the Williamson Laboratory of the Medical College, from the Gynaecological Department, St. Bartholomew's Hospital, London, and from St. Andrew's Hospital, Dollis Hill)

Much attention has been paid in recent years to a possible relation between ovarian function and the development of adenocarcinoma of the endometrium. Marital status and previous pregnancies have been studied by Healy and Brown (1939), and delayed menopause followed by the development of endometrial carcinoma by Crossen and Hobbs (1935), Randall (1945), Masson and Gregg (1940), and Taylor and Millen (1938). A great deal has been written on a possible connexion between endometrial hyperplasia and the development of carcinoma (Novak and Yui, 1936 ; Jones and Brewer, 1941 ; Howard Taylor, 1932). The high incidence of corpus carcinoma with granulosa- and theca-cell tumours has been studied by Schröder (1922), Dockerty (1940), Hodgson, Dockerty, and Mussen (1945), Banner and Dockerty (1945), and Hertig (1945). Recently a paper by Woll, Hertig, Van S. Smith, and Johnson (1948) has drawn attention to the presence of cortical granulomata and thecomatosis in association with adenocarcinoma of the endometrium.

Case 1

On June 5, 1947, a married woman aged 81, with three children, was operated upon. A large combined Brenner tumour and pseudomucinous cystadenoma of the left ovary, together with a small cystic right ovary and the uterus, were removed (W.S.). An early adenocarcinoma of the endometrium was found in the uterus. The large tumour was a typical combined Brenner tumour and pseudomucinous cystadenoma. The case was examined with some care histologically, because it was hoped to investigate the cause of uterine bleeding with Brenner tumours. In the right ovary was a small Brenner tumour together with a cystoma, but the mesovarium contained unusual cells. The cells were localized to the part of the mesovarium immediately adjacent to the cortex of the ovary, approximately at the level of the white line. The cells were large and polyhedral and the protoplasm stained deeply with eosin. The nuclei were large and spherical (Fig. 1) and the cells were superficially similar to the paralutein cells of a mature corpus luteum.

The appearance of the cells suggested that they were in a state of activity, and from their resemblance to paralutein cells it seemed reasonable to believe that they were secreting a hormone-like substance. The rete ovarii also showed some activity. The patient was aged 81, so there was no question that the cells were derived from follicles. Moreover, the location of the cells was quite different from that of Graafian follicles. At the time it was believed that the cells were probably oestrogenic, and it was thought that they might be responsible for the myohyperplasia found in the uterus and might explain the post-menopausal haemorrhage encountered with Brenner tumours.

FIG. 1.—Cells under high magnification (Case 1). Although mainly polyhedral, their shape varies. In the lower part of the photograph the cells seem to be fused together. The characteristic rounded nuclei of the cells can be seen. These cells were found near the hilum at the level of the white line.

Case 2

On Sept. 24, 1947, a nulliparous married woman, aged 40, was operated upon (W.S.) for what was believed to be metropathia haemorrhagica. There was a history of amenorrhoea followed by continuous bleeding. The uterus was found to be slightly enlarged, and the right ovary was palpably about twice the normal size. A subtotal hysterectomy and a right salpingo-oophorectomy were performed. At operation the right ovary was found to be symmetrically enlarged and not to con-

*Received for publication on June 25.

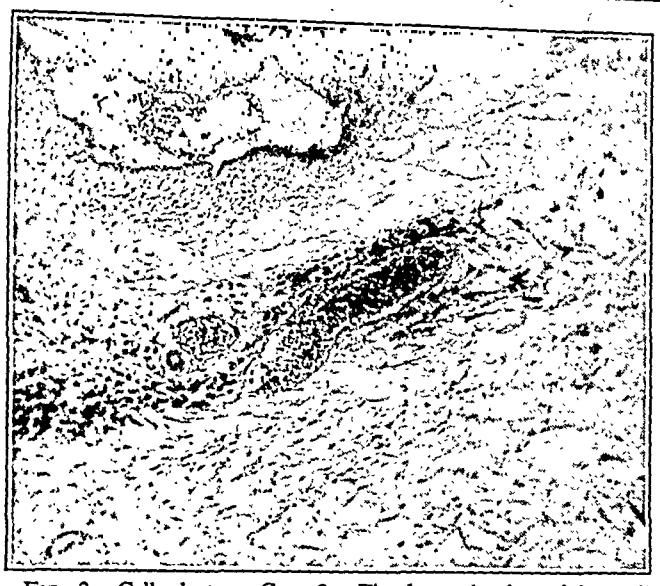

FIG. 2.—Cell clusters, Case 2. The large deeply staining cells which surround the blood vessel in the middle of the photomicrograph are the cells which we describe. The cells seem to be spreading out from the wall of the blood vessel. The light area represents the medulla of the ovary, while, to the left and above, the deeply staining cells form part of the cortex. The cells shown to the left are better differentiated than those which surround the vessel in the centre.

tain a cyst. The endometrium was not polypoidal and was only slightly irregular to the naked eye. The specimen was examined histologically, when a very early adenocarcinoma of the endometrium was found. The tumour was only a few millimetres in diameter.

Comment on Cases 1 and 2

For various reasons it was felt that these two cases should be investigated in detail and reported in the literature.

It was not until March, 1949, that we were able to start work on these and other cases. Case 2 was clearly of an unusual type; consequently the ovary which had been removed was examined in great detail. It contained a small number of primordial follicles, a normal number of interstitial cells, but no corpus luteum and no active Graafian follicle. To our surprise we found deeply staining polyhedral cells in the ovarian medulla which were morphologically identical with those found in Case 1. The identification of the cells was much more difficult than in the first case, for the patient was aged 40 and it was essential to prove that the cell clusters were independent of the follicle system. We have had some experience of ovarian histology and in the past have investigated the morphology of Graafian follicles (Shaw, 1927a), atretic follicles (Shaw, 1925), corpora lutea, and interstitial cells (Shaw, 1926). We concluded that the cells were independent of the follicular system and were not derived from either granulosa or theca interna cells. The analysis was rigorous and critical. No atretic body was found in the vicinity of the cells. The cells were localized to the medulla and the cell clusters were found in separate parts of the ovary without any communication between the clusters. The cells were mainly polyhedral, with rounded nuclei, but sometimes they were fusiform and sometimes stellate. In other areas they were syncytial-like, with the protoplasm of adjacent cells fusing together. The unusual forms of cells found in chocolate cysts have been investigated previously (Shaw, 1927b; Shaw, 1933), and the cell clusters identified in this specimen were different from any of the types of cell found with chocolate cysts of the ovaries. In this case the cells were not located to the subcortical area of the mesovarium but had spread into the medulla. (Photomicrographs of the cells are shown in Figs. 2–5.)

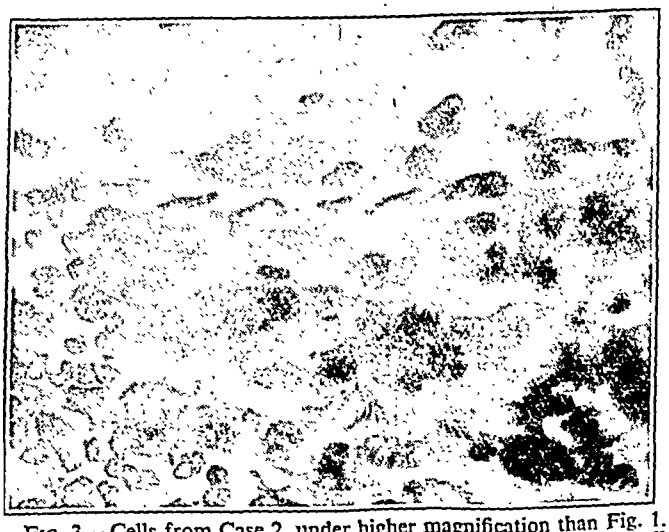

FIG. 3.—Cells from Case 2, under higher magnification than Fig. 1. The same rounded nuclei and the same peculiarities of the cell outline can be seen.

FIG. 4.—Case 2, illustrating the close relation of the cells to the endothelium of the blood vessels. The syncytial-like appearance of the cells is well shown. Above lies the lumen of the vessel with red blood corpuscles.

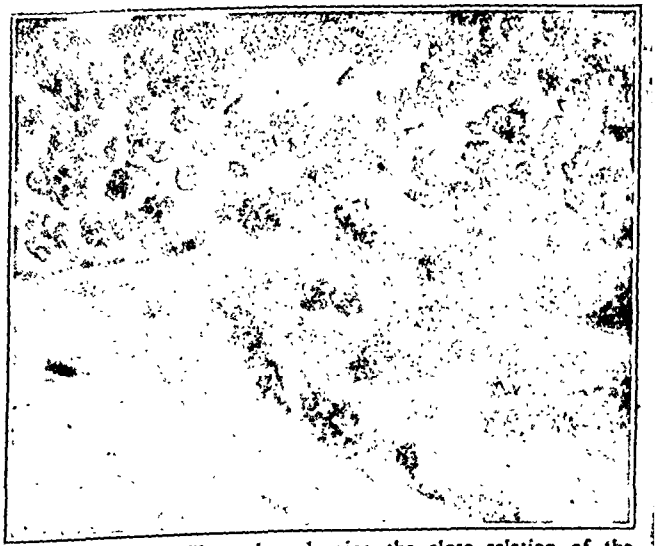

FIG. 5.—Another illustration showing the close relation of the cells to the endothelium. The lumen of the vessel lies in the upper part of the photograph.

As a result of the investigation of these two cases it emed possible that the cell clusters might have some ation to the development of an adenocarcinoma of the dometrium.

Case 3

A married woman, aged 57, had been treated in 1940 by e of us for menopausal haemorrhage by means of an intra-erine application of 50 mg. of radium for 48 hours. The tient was nulliparous. She was admitted to hospital on arch 10, 1949, complaining of vaginal haemorrhage of 14 ys' duration. A biopsy combined with curettage of the rvical canal was carried out next day, and a squamous-celled rcinoma was demonstrated in the specimen. On March 25 Schauta operation was performed (W.S.) and both ovaries ere removed. The uterus contained an early endocervical rcinoma. The ovaries were shrunken.

In view of the findings in the first two cases, both ovaries ere examined in great detail. The same cell clusters found the first two cases were demonstrated in the vicinity of the hite line in one ovary. The cells had the typical appearance f those found in the other cases. The cell clusters were also ound in the second ovary. Some were localized to the vicinity f the white line, while others were identified in the medulla n the neighbourhood of strands of hyaline tissue.

Case 4

A single woman, aged 51, was admitted to hospital on May 18, 1949, complaining of lower abdominal pain and irregular post-menopausal haemorrhage. Curettage was performed by the house-surgeon, and the pathologist reported that the material removed suggested that the patient had an endocervical carcinoma. Because of this report a Wertheim operation was performed on May 27 (W.S.). The growth was found to be an adenocarcinoma of the endometrium, and it was clear that the material removed at the curettage was the lower pole of a polypoidal projection. The ovaries were examined in detail. They were more vascular than normal. They contained no Graafian follicles and no recently atretic follicles. Again, the cell clusters were found in the hilum of one ovary n the mesovarium at the level of the white line. The cells ave been found, up to the present, in only one ovary. In this ase the cell clusters were less numerous than in the first three ases. On the other hand, the carcinoma was more advanced.

Examination of Controls

At this stage of the investigation it became obvious that controls must be examined, although one of us has spent much time upon the histology of the normal ovary and could not recall seeing such cells previously. It was realized, however, that much of this previous work had dealt with the follicular system. One of us has a large collection of slides of ovaries obtained from the Williamson laboratory. They have been regarded in the past as being extremely valuable, and were removed from the laboratory before the war. The slides are numbered in accordance with the registration system of the laboratory.

One evening some 200 of these slides were examined, and in only one were the cell clusters discovered. The next day it was possible to identify the slide. The specimen had been obtained in 1932 by a Wertheim operation (W.S.) performed upon a multipara of 55. In this case the carcinoma was endocervical in type and a pyometra had developed in the cavity of the uterus above the level of the carcinoma. Although the report given from the laboratory stated that the ovaries were normal, one of us had a vague feeling that he had seen the cells as long ago as 1932 and had been puzzled by them but had not investigated them further. After the identification of the cell clusters in this fifth case of carcinoma of the uterus, particularly as the identification had been made without any possibility of bias, we became convinced that the cell clusters had some association with adenocarcinoma of the endometrium and cervical canal.

The next step was to examine the collection of slides in the Williamson laboratory. One of us had been in charge of the laboratory when it was started, and had insisted that every slide and every paraffin block should be stored. Unfortunately, the collection was badly damaged by bombing, and only with the greatest difficulty have old slides been found and identified. Moreover, it seems almost impossible to sort out the paraffin blocks, with the result that the investigation of the specimens is imperfect and incomplete. We have collected together 58 specimens of ovaries from cases of carcinoma of the uterus. We have thought it best to group the cases into those of adenocarcinoma of the endometrium, endocervical carcinoma, and squamous-celled carcinoma of the vaginal portion of the cervix. The results are as follows:

Adenocarcinoma of the endometrium.—Total specimens, 48 (cell clusters found, 24; no cells found, 24).

Endocervical carcinoma.—Total specimens, 9 (cell clusters found, 6; no cells found, 3).

Squamous-celled carcinoma of the portio.—Total specimens, 1 (cell clusters found, 0; no cells found, 1).

The interpretation of these figures is important. The four cases completely investigated were all positive. In the third of these four cases many sections were made before the cells could be identified. In all cases, apart from these four, only one slide of the ovaries has been available. Consequently the negative findings are not regarded as conclusive. We believe that it may be necessary to make a large number of sections from an ovary before the cells can be identified. The small number of cases of squamous-celled carcinoma of the portio is explained because carcinoma of the cervix has usually been treated with radium at St. Bartholomew's Hospital. We are not prepared to draw any conclusions about the incidence of cell clusters in squamous-celled carcinoma of the portio from the material we have at our disposal.

We must stress the difficulty of demonstrating the cells. If they are aggregated in the mesovarium, at the level of the white line, in close proximity to the edge of the cortex, they can be recognized without much difficulty. If, however, they are scattered through the medulla it may be necessary to examine the whole ovary fairly extensively before they can be demonstrated. The size of the cells and their deep staining with eosin help in their recognition. In no case have we found a large number of cells, and we do not regard their detection as being particularly simple.

We have not been able to trace any reference to the cells in the literature. It seems highly improbable that they have not been recognized before and we believe that some previous description will be found.

Significance of the Cells

The number of cases examined is small and we are unlikely to be able to collect a large number of specimens in the immediate future. We have therefore thought it advisable to publish these results so that a wide search can be made in other laboratories. We are convinced that the cells are found in association with carcinoma of the endometrium and cervical canal. It may be that time will show that our work on control specimens has been incomplete, and that similar cells will be found in ovaries not associated with carcinoma of the uterus, but that is not our belief at the present time. Furthermore, at this early stage of the investigation any views that we may put forward are conjectural, hypothetical, and perhaps unsound.

In our view the cells are carcinogenic and lead to the development either of an adenocarcinoma of the endometrium or of an endocervical carcinoma of the cervix. At the moment we have insufficient evidence to show that there is a relation between the cell clusters and the development of squamous-celled carcinoma of the portio. Against this view is the possibility that the cell clusters appear as the result of the stimulation of the ovaries by the carcinoma, and it may be that both the cell clusters and the carcinoma are induced coincidentally by some third factor. The dominance of the uterus by the ovaries has always been the main theme of our previous work on the ovaries. Indeed, the cells of the cell clusters are so similar in type to granulosa-lutein and theca-lutein cells that we feel that the cell clusters are the cause and the uterine cancer the effect.

We are of course familiar with the literature on the development of adenocarcinoma of the endometrium in the absence of both ovaries; three cases were recorded by G. Van S. Smith (1941). We are also acquainted with the large number of cases of stump carcinomata arising after subtotal hysterectomy. Nevertheless, only very few cases of adenocarcinoma of the endometrium arising after the removal of both ovaries are on record. It is possible that cell clusters may be found in the mesovarium further along the ovario-pelvic fold, and that such cells left behind at operation initiated the adenocarcinoma in the cases described. The stump-carcinoma cases arising after the removal of both ovaries cannot be explained by the theory we have put forward. Although it is well known that in many of the cases the carcinoma was already present before the hysterectomy was performed, we must accept the view that a stump carcinoma may develop in the absence of both ovaries. It may be that these cases are mainly squamous growths of the portio.

The frequent localization of the cell clusters to the specific zone in the vicinity of the white line seems to us to be of the utmost significance. We believe that this area should be regarded as an organizing centre for activating cells which are carcinogenic to the endometrium of the body of the uterus and of the cervical canal.

Origin of Cells

We believe that the cells described above are not found either in the normal ovary or in the hilum of the ovary of patients who are not suffering from carcinoma of the uterus. An attempt has been made with the material at our disposal to trace the origin of the cells. Case 2 was of much interest, because the cell clusters seemed to be spreading not only into the medulla of the ovary but circumferentially between the medulla and the cortex. The variation in shape and the syncytial-like arrangement of the cells imply that they were actively dividing. They were invariably found in the vicinity of blood vessels, and we believe that we have traced their origin from the endothelium of small capillaries and of lymphatics. Neither of us is a trained cytologist, so that this opinion may be of little value.

If, however, our main thesis is correct, that the cell clusters are carcinogenic to the endometrium of the body of the uterus and the cervical canal, some attempt must be made to explain why the cell clusters appear. The obvious interpretation is that a hypothetical hormone causes the cells to develop from the endothelium of the blood vessels or lymphatic spaces. This implies that the cause of carcinoma of the endometrium and cervical canal is not a local phenomenon. We realize that such a possibility may alter previous views on the development of carcinoma.

Other lines of investigation present themselves immediately. We feel that wherever possible ovaries from cases of carcinoma arising elsewhere in the body should be examined histologically. This is particularly so in the case of carcinoma of the breast, for there is evidence that malignant disease of the breast sometimes retrogresses after the removal of both ovaries. A similar investigation might be made of the testis and epididymis in cases of carcinoma of the prostate.

Case 3 is of some importance gynaecologically. The patient had been treated previously with radium and an artificial menopause had been created. Although the follicular system in the ovaries had retrogressed completely, the cell clusters were found not only near the white line but also in the medulla. The findings suggest that the cells appear after the creation of an artificial menopause, and that many of the puzzling features of the development of carcinoma of the endometrium after radiotherapy can be explained. Again, in the radium treatment of carcinoma of the uterus it seems that the cells must first be destroyed by radium, otherwise a recurrence of carcinoma is to be expected. It seems to us important to determine whether the cells clusters disappear after the application of radium to the cervix. If the cell clusters are not destroyed, and our thesis that they are carcinogenic is correct, the procedure in such cases should be to remove the ovaries before radium treatment is instituted.

Conclusions

Unusual cells have been demonstrated in the mesovarium and medulla of the ovaries of cases of adenocarcinoma of the endometrium and of endocervical carcinoma of the uterus. So far as we know, the cells have not been described before. If they have been described, little attention has been paid to them. The cells do not seem to be found in normal ovaries, and their presence seems to be restricted to cases of carcinoma of the uterus. They are usually found in the mesovarium, close to the termination of the cortex of the ovary, but they may also be found in the ovarian medulla and, very rarely, in the cortex. Although they may possibly appear as the result of some reaction from the uterine carcinoma or may be stimulated to appear by a hypothetical factor which also initiates the carcinoma of the uterus, we incline to the view that they are carcinogenic. Our main difficulty has been to obtain material.

In only four cases have the ovaries been investigated in great detail. In 54 other cases of carcinoma of the body of the uterus and carcinoma of the cervix, only one slide of one ovary has been available. Of these 54 cases the cells have been found in 26. We emphasize the difficulty of identifying the cells, and we firmly believe that the cells would have been found in a larger number if the whole of the ovaries had been available for examination. Nevertheless, even in this small and imperfect series the incidence of the cells is appreciable. We feel that further investigations should be made, and if specimens are removed and suitable laboratory facilities are not available we hope that the specimens will be sent to us for examination. The number of cases of squamous-celled carcinoma of the portio available for investigation is surprisingly small, and we are not prepared to offer any comment on the association of the cells with the development of this form of cancer of the uterus.

Summary

Unusual cells have been demonstrated in the mesovarium and ovarian medulla of cases of adenocarcinoma of the endometrium and of endocervical carcinoma.

The cells are secretory in type, yet differ morphologically rom any ovarian cells known to us.

They have not been discovered in control cases.

They are found only in relatively small numbers and may e extremely difficult to detect. A single section through the vary is insufficient, as a general rule, to demonstrate them.

The cells may possibly be carcinogenic, secreting a hormone hich stimulates some of the cells of the endometrium of the ody of the uterus and cervical canal to undergo malignant hange. It is hoped that a further search for them will be made n other laboratories.

Our thanks are due to Mr. Bert Cambridge, of the Williamson aboratory, for his great help, particularly in sorting out microscope ides from bomb debris, and to Mr. Norman K. Harrison, A.R.P.S., f the photographic department, who has offered every possible acility. Miss J. E. Colley has given secretarial help enthusiastically t unusual times of the day, and her knowledge of the literature has een most useful. Miss Joan Wheelwright has followed the work ith great interest, instilling the optimism of youth at the most ritical phase of the investigation.

INFANTILE DIARRHOEA AND VOMITING

A CLINICAL AND BACTERIOLOGICAL INVESTIGATION

BY

JOAN TAYLOR, M.B., B.S., B.Sc., D.P.H.
From the Salmonella Reference Laboratory, Central Public Health Laboratory, Colindale

B. W. POWELL, M.B., M.R.C.P., D.C.H.
Working full-time for the Medical Research Council; from the Hospital for Sick Children, Great Ormond Street

AND

JOYCE WRIGHT, D.M.
Member of the Medical Research Council's Scientific Staff from the Research Laboratories of the Hospital for Sick Children, Great Ormond Street

This paper reports the results of a combined clinical and bacteriological investigation of infantile diarrhoea and vomiting, and includes a note by Dr. F. O. MacCallum on his virus investigations. In order that cases of infective origin should be presented for bacteriological study the clinical material was drawn in the main from outbreaks of diarrhoea and vomiting and from intercurrent attacks in hospital wards. In addition there were included two series of cases admitted consecutively to the gastro-enteritis units of a children's hospital and of an infectious diseases hospital. In these groups there was sometimes uncertainty whether cases should be classified as "infective," "dietetic," or "secondary to parenteral infection."

The first outbreak occurred in the nurseries of a maternity unit, and a number of observers took part in its investigation. Subsequently the course of each outbreak and the clinical progress of each case were followed by one paediatrician. Material for bacteriological examination was dealt with at a centrally placed laboratory as soon as possible after collection. In this way a wide area of field investigation could conveniently be covered. The methods and results of the general bacteriological investigation of the cases are given in a later section.

The detailed study by Crowley *et al.* (1941) left little expectation that a bacterial agent might be determined by a quantitative comparison of the faecal flora of affected and unaffected babies. From the outset of the present investigation it had seemed that bacterial studies would need to follow the modern trend towards subdivision of genera by serological, biochemical, and phage-typing methods. Primary culture plates or subcultured strains were therefore sent to laboratories specially equipped for their detailed examination. Similarly, for virus studies, post-mortem tissues and other material were submitted to a laboratory engaged in virus research.

Previous investigators (Costello and Lind, 1939; Sakula, 1943; Sevitt, 1945; Light and Hodes, 1943; Buddingh and Dodd, 1944) have found a variety of bacterial and virus agents associated with infantile diarrhoea and vomiting. Bray (1945) isolated a particular serological type of *Bact. coli var. neapolitanum* from 42 out of 44 cases of infantile "summer diarrhoea." From an early stage of our investigation, work on a certain type of *Bact. coli* provided a promising line to pursue. Sera for its identification were prepared from the *Bact. coli* strains of infants suffering from epidemic diarrhoea of the newborn. The outbreak in which these cases occurred is described under Group A below. The strain is referred to throughout the paper as *Bact. coli* D 433. A description of the serological work, together with an account of the biochemical activities and other characters of the strain, are given in a later section.

The main purpose of this paper is to report the association of *Bact. coli* D 433 with certain groups of cases of infantile diarrhoea and vomiting and its absence in control groups of healthy and sick babies. Work on similar lines was published by Giles and Sangster in March, 1948. They reported the isolation of a serologically homogeneous strain of *Bact. coli* from over 90% of cases of primary infective gastro-enteritis admitted to hospital during an outbreak in the city of Aberdeen in 1947.

Cases of Infantile Diarrhoea and Vomiting

Clinical and bacteriological investigations were made on the following groups of infants suffering from diarrhoea and vomiting: one outbreak in a maternity unit (Group A); two outbreaks in a mothers and babies' hostel (Groups B and C); one outbreak in a residential nursery (Group D); intercurrent cases of diarrhoea and vomiting in a children's hospital (Group E); routine admissions to two gastro-enteritis units (Groups F and G); and endemic diarrhoea and vomiting in a residential nursery (Group H).

Group A

An outbreak of epidemic diarrhoea of the newborn occurred in February and March, 1947, in the 90-bed maternity unit of a Derbyshire hospital. In all, 20 babies contracted the disease and 14 of them died. At the onset of the illness the age of 19 of the babies was from 6 to 20 days, and that of one baby, retained for the treatment of minor sepsis, was 43 days. All the babies had received early glucose feeds.

Fifteen were fully bottle-fed and four partially breast-fed at the time when the illness began; one baby, apart from early glucose feeds, had been fully breast-fed from birth.

The outstanding symptom was diarrhoea with frequent watery green or yellow stools, preceded in some cases by a period of lethargy, reluctance to feed, and loss of weight. Vomiting also occurred in all cases. Parenteral infection was limited to one case of early bronchopneumonia, some subcutaneous abscesses, and a few minor skin infections. All the babies became dehydrated, most of them severely so.

Nine babies were available for examination during the active stage of the disease, and *Bact. coli* D 433 was isolated from all of them. Five had developed symptoms after discharge from the maternity unit and were readmitted for treatment in the emergency gastro-enteritis unit. The duration of illness at the time of swabbing varied from two to five days. In eight cases the strain was isolated from the rectal swabs and in one case from the upper respiratory tract only.

Group B

A severe and sudden outbreak of diarrhoea and vomiting occurred in a mothers and babies' hostel in Middlesex between Sept. 7 and 18, 1947. The hostel has accommodation for 14 mothers and their babies. They are usually admitted direct from maternity hospitals after the lying-in period. The babies are cared for by their mothers, under the supervision of a small staff of nurses. Of the 12 babies living in the hostel at the time 11 developed the disease. The one baby who remained healthy was fully breast-fed. The others were all bottle-fed babies who had thrived since birth and were in good health at the start of the outbreak. Their age distribution was as follows: under 1 month, 3; 1 month, 3; 2 months, 2; 3 months, 2; 4 months, 1. One other baby, the 9-months-old non-resident child of the daily cleaner, also contracted diarrhoea and vomiting; he was taken into the kitchen each day for his midday meal.

The main symptoms were diarrhoea and vomiting, with dehydration. In several cases the onset was heralded by lethargy and reluctance to take feeds. The stools were green and watery, with mucus but no blood (except as a terminal event in one fatal case). Vomiting occurred in all but two cases; it was severe in four. There was no evidence of parenteral infection at the start of the illness, but secondary infection occurred in several cases during its course. Some degree of dehydration occurred in all the 12 cases; it was slight in two and severe in the remainder. Two cases may therefore be classed as mild and 10 as severe. Seven babies were given intravenous therapy, and these recovered. There were three deaths.

Rectal swabs were taken, at times varying from the second to the eighth day of illness, from 10 of the 12 sick babies in this outbreak. *Bact. coli* D 433 was present in all of them.

Group C

A second and less severe outbreak of diarrhoea and vomiting occurred in the same hostel eight months after that of Group B. Eight of the 17 babies exposed to infection developed the disease between May 13 and June 6, 1948. Seven of the eight were bottle-fed, and one, a mild case, was breast-fed. Seven of the babies were 1 month old and one was 2 months. The clinical features were similar to those of the previous outbreak, but with two exceptions the cases were comparatively mild.

The onset of illness was more insidious than in the previous outbreak, and in three cases was characterized by lethargy and reluctance to feed. The stools were green and mucoid—watery in the severe cases and relaxed in the mild ones. Vomiting occurred, but was never a severe feature. Three of the babies had no more than slight diarrhoea of a few days' duration, accompanied in one by loss of weight and in the others by a temporary interruption of weight gain. Ordinarily these very mild cases might not have been regarded as infective diarrhoea, but it was considered that they were part of the outbreak and therefore mild examples of the disease. The remaining five babies were more severely ill; two became dehydrated, and one of these died.

Bact. coli D 433 was isolated from the rectal swabs of the eight babies with diarrhoea and vomiting. The swabs were taken in five cases on the first, second, or third day of illness, and in the other three cases on the twelfth, fourteenth, and fifteenth days. Rectal swabs had been taken from three babies before the onset of symptoms. *Bact. coli* D 433 was isolated from one baby on seven occasions during the nine days preceding onset and from the other two babies on the preceding one and four days.

Group D

An investigation was made of an outbreak of diarrhoea and vomiting in a residential nursery in Hertfordshire. It has accommodation for 40 children, including a nursery unit for 12 babies. At the end of December, 1947, two babies died from diarrhoea and vomiting; these are not included in the series. Four others developed the disease between Feb. 1 and 15, 1948. They were all bottle-fed. Their ages were as follows: 1 month, 1; 2 months, 2; 3 months, 1. The symptoms were severe diarrhoea with green watery mucoid stools and vomiting. No parenteral infection was found at the start of the illness. All the babies became dehydrated. One baby died after an illness of eight days.

Bact. coli D 433 was present in the rectal swabs of the four cases. The swabs were taken from the fourth to the six... day of the illness.

Group E

An investigation was made of 23 babies who developed intercurrent diarrhoea and vomiting while undergoing in-patient treatment in a children's hospital in London. The occurrence of seven cases in one ward during a period of two months, and of two or three cases in quick succession in three other wards suggested the possibility that some, if not all, of them were of an infective type. The babies were all nursed in single cot cells.

The period of study was from late January to early May 1948. The babies were all bottle-fed or on mixed feeding. Their ages were as follows: under 3 months, 5; 3 to 5 months 8; 6 to 8 months, 6; 9 to 11 months, 3; over 1 year, 1. They had been admitted to hospital for a variety of conditions—i.e., feeding difficulty, rumination, congenital defect, eczema, surgical operation, etc. The attack of diarrhoea and vomiting was characterized by the onset of watery diarrhoea, accompanied in most cases by vomiting. Parenteral infection at onset was found in only two cases. Seventeen of the babies became severely ill and 16 were given intravenous therapy; the other babies had moderate or mild attacks. Two of the babies died.

Bact. coli D 433 was present in the rectal swabs of 21 of the 23 cases of intercurrent diarrhoea and vomiting. The swabs were taken at times varying from the first to the ninth day of illness.

Group F

An investigation was made of 26 cases of diarrhoea and vomiting admitted consecutively between Feb. 4 and March 3, 1948, to the gastro-enteritis unit of a children's hospital in London. The unit consists of one double-cot and eight single-cot cells. Twelve of the 26 babies had developed intercurrent diarrhoea and vomiting while in other wards of the hospital or shortly after their discharge from them. These cases have already been included in Group E.

The other 14 infants with diarrhoea and vomiting were admitted from outside at the request of medical practitioners. They were all bottle-fed or on mixed feeding. Their ages were as follows: under 3 months, 5; 3 to 5 months, 3; 6 to 8 months, 4; over 1 year, 2. On admission nine of the babies had been ill for periods varying from one to six days and five for three weeks or more; three had suppurative otitis media, one severe proctitis, and one a history of recent coryza. Seven were severely ill and were given intravenous therapy.

Bact. coli D 433 was present in the rectal swabs of six of the 14 cases; with few exceptions the swabs were taken on the day of admission to the unit. Of these six babies three had contracted diarrhoea and vomiting in other hospitals, two during outbreaks in residential nurseries, and one, a sporadic case, at home. The eight babies from whom the strain was not isolated had developed the disease at home.

Group G

An investigation was made of 24 cases of diarrhoea and vomiting admitted consecutively during May, 1948, to a gastro-enteritis unit, consisting of 48 single-cot cells, in a London infectious diseases hospital. From each baby a rectal swab was taken in the receiving-room before admission to the unit, and a nasopharyngeal and repeat rectal swab on the following day within the unit.

Two of the 24 babies were partially breast-fed; the remainder were either bottle-fed or on a mixed diet. Their ages were as follows: under 3 months, 7; 3 to 5 months, 11; 6 to 8 months, 3; 9 to 11 months, 3. Three had contracted the disease while in another hospital, four while in a residential nursery, and 17 at home. A history of contact with other cases of infantile diarrhoea and vomiting was found in nine instances.

The clinical picture and the severity varied considerably. Diarrhoea was the main symptom in all cases, and vomiting occurred in all but a few, although it was marked in only five. Parenteral infection was found on admission in eight babies (upper respiratory tract infection, 5; bronchopneumonia, 2; vaccination reaction, 1). On admission 17 cases were classified as mild and seven as severe; in the latter group six were sufficiently dehydrated to need intravenous therapy. Seventeen made uneventful recoveries, four (one of whom died) had severe relapses, and three developed secondary parenteral infections (bronchopneumonia, 2; skin sepsis, 1).

Twenty-one of the 24 babies were admitted during the first week of the disease, two in the second week, and one, with a relapse and pneumonia, in the seventh week. *Bact. coli* D 433 was present on admission in three of the seven severe cases and in two of the 17 mild ones. There were no obvious clinical features to distinguish those cases in which the strain was found. Two of the five babies in whom *Bact. coli* D 433 was present had contracted diarrhoea and vomiting while undergoing treatment in another hospital; the other three were admitted direct from home.

Group H

A mild type of endemic infantile diarrhoea and vomiting was investigated in a large residential nursery in London. Accommodation is provided for 120 children under 3 years of age, including about 40 bottle-fed or breast-fed babies. There is a large turnover of children, with frequent admissions and discharges. On arrival some of the babies are in poor physical condition and are under weight. Rises in incidence of the endemic diarrhoea and vomiting occur from time to time. A period of comparative freedom from the disease was followed by an increase in the number of cases during March and April, 1948.

Investigations were made of 14 cases occurring consecutively during this time. The babies affected were all either bottle-fed or on mixed feeding. Their ages were as follows: under 3 months, 8; 3 to 5 months, 3; 6 to 8 months, 1; 9 to 11 months, 1; over 1 year, 1. Diarrhoea and vomiting, usually of insidious onset, were the main symptoms. Parenteral infections at this stage were found in only two of the babies. Eight showed clinical evidence of dehydration, but only three were severely ill. There were no deaths.

Rectal swabs were taken from the 14 babies at times varying from the first to the sixth day of illness. No *Bact. coli* D 433 was isolated from them.

Control Groups of Babies

Rectal swabs were taken from a control series of 208 babies (Groups K and L). Their ages were as follows: under 3 months, 122 (including 79 under 1 month); 3 to 5 months, 42; 6 to 8 months, 35; 9 to 11 months, 9. Seventy-seven were breast-fed, 43 partially breast-fed, and 88 either bottle-fed or on mixed feeding. Those who had received no more supplementary feeding than water or glucose feeds during their early days have been included in the breast-fed group.

Group K: Healthy Babies.—One hundred and seventy-five healthy babies were examined during the period February–June, 1948. Sixty-seven of them were attending infant-welfare clinics in North and South London, 29 were in residential nurseries in North London and in Hertfordshire, 10 were attending clinics for congenital defects in Central London, and 69 were in the newborn babies' nurseries of three maternity hospitals in East and North London and in Middlesex. No *Bact. coli* D 433 was isolated from the rectal swabs of these 175 babies. After an interval of at least two weeks an inquiry was made about the progress of each baby. Thirteen of them could not be traced. None of the other 162 had developed diarrhoea and vomiting, but it was reported that six neonatal babies had had mild digestive disturbances with relaxed stools.

Group L: Sick Babies.—Thirty-three sick babies were swabbed in the receiving-room of a children's hospital in London immediately before their admission for conditions other than diarrhoea and vomiting. Seventeen of them were examined in May and June, 1948, and 16 in October and November, 1948. No *Bact. coli* D 433 was isolated from their rectal swabs. The clinical progress of each baby was followed for a fortnight after admission; none of them developed diarrhoea and vomiting during this time, but five of them had some relaxed stools while in hospital.

Incidence of Bact. coli D 433

The accompanying Table shows that *Bact. coli* D 433 was present in all the 31 cases of infective diarrhoea and vomiting which were swabbed in four outbreaks of the disease

Table showing Incidence of Bact. coli D 433 in Cases of Diarrhoea and Vomiting and in Control Groups of Babies

Group	Place	Description of Group	No. of Babies Swabbed	Bact. coli D 433	
				No. of Babies Positive	Percentage of Babies Positive
A	Maternity unit	Epidemic diarrhoea of the newborn 20 cases, 14 deaths	9	9	100
B	Mothers and babies' hostel	Severe outbreak. 12 cases. 3 deaths	10	10	100
C	Mothers and babies' hostel	Second and less severe outbreak in same hostel as Group B. 8 cases. 1 death	8	8	100
D	Residential nursery	Severe outbreak. 4 cases. 1 death	4	4	100
E	Children's hospital	Intercurrent cases among sick babies 17 severe and 6 moderate or mild cases. 2 deaths	23	21	91
F	Gastro-enteritis unit 1 (children's hospital)	Routine admissions. 7 severe and 7 moderate or mild cases. No deaths	14	6	43
G	Gastro-enteritis unit 2 (infectious diseases hospital)	Routine admissions. 7 severe and 17 mild cases. 1 death	24	5	21
H	Residential nursery	Endemic diarrhoea and vomiting. 3 severe and 11 mild cases. No deaths	14	0	0
K	Clinics, maternity units, and residential nurseries	Healthy babies	175	0	0
L	Receiving-room of children's hospital	Sick babies on admission for conditions other than diarrhoea and vomiting	33	0	0

(Groups A–D) and in 21 out of 23 intercurrent cases in a children's hospital (Group E). The strain was not, on the other hand, isolated from any of the 14 cases of endemic diarrhoea and vomiting in a large residential nursery (Group H). *Bact. coli* D 433 was present in six of the 14 cases admitted direct to gastro-enteritis unit 1 (Group F), but was found in only five of the 24 cases admitted to gastro-enteritis unit 2 (Group G). It was not isolated from any babies in the control group, which consisted of 175 healthy babies and of 33 sick babies suffering from conditions other than diarrhoea and vomiting.

The great majority of the babies from whom *Bact. coli* D 433 was isolated had severe attacks of diarrhoea and

vomiting, with enough dehydration to need intravenous therapy. Some of the cases in which it was found were, however, mild examples of the disease.

An analysis of the age distribution of the 63 babies in whom *Bact. coli* D 433 was present gave the following results: under 3 months, 33; 3 to 5 months, 15; 6 to 8 months, 11; 9 to 11 months, 4. The first age group included 13 babies in the neonatal period, eight of whom were involved in the outbreak of epidemic diarrhoea of the newborn (Group A). The ages of the babies in the outbreak of Group B were of interest in that they ranged from 25 days to 9 months. The limits of age, taking the whole series of cases showing *Bact. coli* D 433, was 10 days for the youngest baby and 11 months for the oldest.

Further Observations on Cases.

1. *Necropsies.*—Post-mortem examinations were carried out on 13 babies of Groups A–E. The seven neonatal babies all showed hyperaemia of the intestines, particularly of the small intestine; in all but one case there was some enlargement of the mesenteric glands. Two small membranous lesions of the gastric mucosa were found in one of these seven babies, and a few large superficial erosions of the small intestine in another. No evidence of parenteral infection other than one case of early bronchopneumonia was found. Among the group of six older babies four showed some hyperaemia of the small and large intestines; the alimentary tract of the other two appeared normal. In five of these cases the liver showed fatty change. The only parenteral infections found were pneumonia and mastoiditis in one case. A sample of the contents of the small intestine was taken at necropsy from four of the neonatal and three of the older babies. *Bact. coli* D 433 was present in all these specimens. It was also present in the mastoid antra of the baby with mastoiditis. The interval from the onset of diarrhoea and vomiting to death varied from three to 27 days. One of the 13 dead babies had not been swabbed during life.

2. *Nasopharyngeal Swabs.*—Nasopharyngeal as well as rectal swabs were taken from 88 of the babies suffering from diarrhoea and vomiting. *Bact. coli* D 433 was isolated from the nasopharyngeal swabs in 12 cases; 11 of these yielded the strain in the rectal swabs also. Five of these 12 were suffering from epidemic diarrhoea of the newborn (Group A).

3. *Chemotherapy.*—Sixteen babies were on courses of sulphonamides (sulphadiazine, sulphamezathine, sulphasuxidine, or phthalyl sulphathiazole) and three on penicillin treatment when *Bact. coli* D 433 was isolated from their rectal swabs.

4. *Infant Feeding.*—An analysis was made of the feeding of those babies from whom *Bact. coli* D 433 had been isolated. It was found that on the day of swabbing and during the previous few days they had received a variety of dried-milk preparations to which had been added sucrose, glucose, lactose, or dextrimaltose. Expressed breast milk or diluted Hartmann's fluid had been given to a few of them. Two of the babies were fully breast-fed and three partially breast-fed.

5. *Later Swabbing of Babies with Diarrhoea and Vomiting*

(a) Clinical Progress and Bact. coli. D 433.—In gastro-enteritis unit 1 a study was made of the association between the clinical progress of the cases and the finding of *Bact. coli* D 433. From the 20 babies concerned, rectal swabs were taken on admission and on each subsequent Monday from early February to the end of March, 1948. Eight of the babies were negative to *Bact. coli* D 433 on admission and six of these became positive during their illness. The first positive swab was discovered at times varying from the 10th to the 30th day after admission. The finding of *Bact. coli* D 433 was in one case associated with a severe exacerbation of diarrhoea and in three others with mild relapses. Of 12 babies who were positive to *Bact. coli* D 433 on admission nine became negative during their stay in the unit. The stools of three had settled by this time, but those of the other six were still relaxed. The first negative swab occurred at times varying from the ninth to the 34th day of illness.

(b) Re-examination of Cases in Groups A–D.—Eighteen other babies (Groups A–D) from whom *Bact. coli* D 433 had been isolated in the first swab were re-examined during the course of their illness. It was not possible to correlate exactly the clinical progress of the cases with the finding of *Bact. coli* D 433. It was observed, however, that in some cases loose stools continued after the rectal swabs had become negative, and that in others the stools had settled while the result was still positive.

(c) Clinical Relapses.—Four babies admitted to gastro-enteritis unit 2 during April and May, 1948, had at first mild or moderate attacks of diarrhoea and vomiting, accompanied in one case by bronchopneumonia. While in hospital they had relapses of their diarrhoea and vomiting during which they all became dehydrated. Three were given intravenous therapy and one of them died. *Bact. coli* D 433 was not isolated from their rectal swabs during the initial attacks, but was present in all four during their relapses.

6. *Cases Other than Diarrhoea and Vomiting.*—During the course of the investigation 14 babies admitted to the gastro-enteritis units were found to have illnesses other than diarrhoea and vomiting. No *Bact. coli* D 433 was isolated from their rectal swabs.

7. *Other Outbreaks of Diarrhoea and Vomiting.*—*Bact coli* D 433 was present in rectal swabs or stools received from a limited number of cases of diarrhoea and vomiting which occurred in other outbreaks during 1948. The residential nurseries in which they arose were situated in three counties. The results of these examinations, taken together with those listed in the Table, show a distribution of *Bact. coli* D 433 over a wide area. In all, it was isolated from cases of diarrhoea and vomiting in Derbyshire Middlesex, Hertfordshire, Berkshire, Leicestershire, Sussex and London.

Adult and Baby Contacts

A number of adult and baby contacts of infective diarrhoea and vomiting were examined for the presence of *Bact. coli* D 433 in their faeces or rectal swabs. Some individuals were direct contacts and others were indirect contacts exposed only to mediate infection or to possible carriers of the infecting agent.

Adult Contacts.—Faeces (or rectal swabs) were obtained from 84 adult contacts of infantile diarrhoea and vomiting. Specimens were taken, usually once only from each person either during or shortly after an outbreak of the disease. Four of the contacts reported diarrhoeal attacks during the course of the investigation of Groups A, B, and H. No *Bact. coli* D 433 was found in their specimens, but in two instances the diarrhoea was not reported until recovery was complete. The other 80 adult contacts were associated with Groups B, C, D, and E, and none of them reported any attack of diarrhoea. *Bact. coli* D 433 was isolated from only four of these 80 persons—a daily cleaner whose baby had an attack of diarrhoea and vomiting, a laundress whose duties included the washing of soiled napkins, and two mothers, one of whom

was the mother of a case. On re-examination of the laundress and the cleaner six and 11 days later, respectively, no *Bact. coli* D 433 was found in their faeces.

Baby Contacts.—Rectal swabs were taken from 34 baby contacts of cases of diarrhoea and vomiting from which *Bact. coli* D 433 had been isolated. Eleven of the baby contacts were associated with the neonatal outbreak (Group A), nine with the outbreaks in the mothers and babies' hostel (Groups B and C), seven with that in a residential nursery (Group D), and seven with cases of intercurrent diarrhoea and vomiting in a hospital ward (Group E). The rectal swabs were obtained once only from 26 of the baby contacts and on several occasions from the other eight. Nine of the 34 baby contacts were positive to *Bact. coli* D 433. Three of these nine were associated with Group A, one with Group B, and five with Group C. Four of the nine babies were breast-fed, two partially breast-fed, and three bottle-fed. The remaining 25 were negative to *Bact. coli* D 433; seven of these were breast-fed, four were partially breast-fed, and 14 either bottle-fed or on mixed feeding. The progress of the 34 babies was followed for a further fortnight, and all remained free from diarrhoea and vomiting. Rectal swabs were also taken from 28 baby contacts of cases of endemic diarrhoea and vomiting (Group H) in a residential nursery. No *Bact. coli* D 433 had been isolated from the babies suffering from the disease and none was found among the baby contacts.

Subsequent Investigations in Nurseries and Hospital Wards

Rectal swabs were taken some months later from infant occupants of the nurseries and wards in which cases of diarrhoea and vomiting associated with *Bact. coli* D 433 had been investigated. The groups present at the later date consisted, with few exceptions, of different babies from those originally there.

(*a*) On three occasions examinations were made of groups of babies in the maternity nurseries in which epidemic diarrhoea of the newborn (Group A) had occurred in February–March, 1948. (1) Three months after the outbreak, in June, 1947, 20 neonatal babies in the nurseries were swabbed. No *Bact. coli* D 433 was isolated from them. Their subsequent progress was not followed. (2) Fourteen and 17 months after the outbreak, in May and August, 1948, two further groups of neonatal babies in these nurseries were examined. The groups consisted of 21 and 30 babies respectively, making a total of 51. The results were unexpected, for a strain of *Bact. coli* which was closely related antigenically to *Bact. coli* D 433 but which failed to produce gas in "sugars" was isolated from 21 of them. Particulars of this anaerogenic strain are given below. A clinical follow-up of the 51 babies was made 2½ weeks after each swabbing. Fourteen had suffered from mild transient diarrhoea; from 10 of these 14 the anaerogenic strain had been isolated. It was evident that the babies were free from severe epidemic diarrhoea of the newborn. It is uncertain whether any significance should be attached to these minor diarrhoeal attacks, which may possibly have been no more than digestive disturbances common in the neonatal period.

(*b*) The infant community of the mothers and babies' hostel were swabbed three months after the second outbreak of diarrhoea and vomiting (Group C) and that of the residential nursery in Hertfordshire three and six months after the outbreak (Group D). There had been no cases of diarrhoea and vomiting in the intervening months. The number of babies present was 13, 10, and 8 respectively. No *Bact. coli* D 433 was isolated from the rectal swabs. Progress reports for the ensuing fortnight showed that none of the babies developed diarrhoea and vomiting during this time.

(*c*) Thirty-one sick babies accommodated in wards where intercurrent diarrhoea and vomiting had occurred in January–May, 1948, were swabbed in August, 1948. The intervening period had been a quiescent one. No *Bact. coli* D 433 was isolated from the rectal swabs of these babies. Their clinical records for the following fortnight showed that one of them had developed diarrhoea and vomiting during this time, and that the others had remained free from the disease.

Report of Virus Investigations by Dr. F. O. MacCallum

Attempts made to isolate a virus from material obtained from four fatal cases of diarrhoea and vomiting yielded negative results.

1. Post-mortem material was obtained from two babies, aged 9 and 17 days, who had died from epidemic diarrhoea of the newborn (Group A). They had been ill for three and five days respectively. Suspensions of brain, small intestine, and intestinal contents were filtered through collodion membranes which had an A.P.D. of 750 mμ. The filtrates were then inoculated into mice, cotton-rats, guinea-pigs, and young swine. Intracerebral passages were made, using 100 mice. The mice were killed after various intervals and brain suspensions injected into further mice. Eight passages were made, with negative results. Six intracerebral passages using 18 guinea-pigs were negative. Four intranasal passages, using 20 guinea-pigs, of the consolidated lung of an intracerebrally inoculated guinea-pig were negative. Four intracerebral passages using 20 cotton-rats were negative. The original swine were inoculated intranasally and orally, and then three passages were carried out with brain intracerebrally, with lung intranasally, and with intestine orally. Seventeen swine were used, and the results were negative.

2. Post-mortem material was obtained from twin babies, aged 3 months, who had died from diarrhoea and vomiting (Group B). They had been ill for 7 and 8 days. Mice were inoculated intracerebrally with brain, intranasally with lung, and orally with intestine. The material was unfiltered. Two passages using 16 mice gave negative results. Similar inoculations in four cotton-rats and four young rabbits gave negative results. Three passages in 18 guinea-pigs were negative.

General Bacteriological Investigations

The number of cases of infantile diarrhoea and vomiting listed in the Table is 106. Rectal swabs from 85 of these were examined on two to four occasions for non-lactose-fermenters and from 18 on one occasion only. Nasopharyngeal and rectal swabs from 88 of the 106 cases were submitted to general bacteriological examination.

Nasopharyngeal swabs consisted of curved swabs which were passed under the uvula to the posterior pharyngeal wall. They were inoculated on to horse-blood–digest-agar plates, which were incubated aerobically. In most cases rectal swabs were taken through a narrow glass anal cannula for their protection from skin contamination. Culture media used were horse-blood digest agar (one plate incubated aerobically and one anaerobically), horse-blood digest agar + 1 in 1,000 chloral hydrate for inhibition of swarming by *Proteus* (Gillespie, 1948), plain digest agar + 7.5% NaCl for isolation of staphylococci (Chapman, 1945), and desoxycholate-citrate medium (Hynes, 1942) or Difco "bacto S S" agar for isolation of non-lactose-fermenters.

No salmonellae or shigellae were isolated from the rectal swabs of the 103 cases examined for non-lactose-fermenters. Thirty-six of the 88 babies from whom nasopharyngeal and rectal swabs were taken had, prior to swabbing, either had diarrhoea and vomiting for more than seven days or had received chemotherapeutic drugs. They have therefore been excluded from the following analysis of the general bacteriological results. The swabs from the remaining 52 babies were taken in 18 cases on the first or second day

of illness, in 21 on the third or fourth day, in 11 on the fifth or sixth day, and in 2 on the seventh day. The distribution of organisms in the 52 nasopharyngeal swab cultures was as follows: alpha- and non-haemolytic streptococci, 48; *Staph. pyogenes*, 30; *Neisseria*, 23; *Bact. coli*, 18; diphtheroids, 7; *Haemophilus*, 5; pneumococcus, 5; yeasts, 3; aerobic spore-bearing bacillus, 1; *Chromobacterium*, 1; paracolon bacillus, 1. The distribution of organisms in the 52 rectal swabs was as follows: *Bact. coli*, 50; *Streptococcus*, 41; *Staph. pyogenes*, 16; *Proteus*, 16; *Lactobacillus*, 15; *Micrococcus*, 15; paracolon bacilli, 5; *Fusiformis*, 3; *Clostridium*, 2; yeasts, 2; aerobic spore-bearing bacillus, 1.

Bact. coli was present in abundance in 47 of the 52 rectal swabs. The detailed examination of the *Bact. coli* strains is described below. Organisms of the *Proteus* group were isolated from 16 of the 52 rectal swabs, but in abundance from only 11 cases. *Proteus* was not isolated from any of the babies with epidemic diarrhoea of the newborn (Group A) or from those with diarrhoea and vomiting in two other outbreaks (Groups B and C). It was, on the other hand, present in the rectal swabs of all the babies in Group D, but it was also present in the seven unaffected baby contacts in this outbreak.

Only seven of the 14 cases with endemic diarrhoea and vomiting (Group H) were suitable for inclusion in the general bacteriological analysis, and *Proteus* was grown from the rectal swabs of three of them; the organism was also found in 16 of the 28 baby contacts in the nursery. Paracolon bacilli were present in the rectal swabs of five of the 52 babies; three of these five were suffering from epidemic diarrhoea of the newborn. Paracolon bacilli were isolated from the nasopharyngeal swab of one of them. *Staph. pyogenes* (i.e., coagulase-positive staphylococci) was present in the nasopharyngeal swabs of 30 and in the rectal swabs of 16 babies; in 15 of the latter it was isolated from the nasopharyngeal swabs also.

Staph. pyogenes strains isolated from the cases of the first two outbreaks (Groups A and B) were examined for phage type by Dr. V. D. Allison. The distribution of the phage types in the nasopharyngeal swabs was type 7/47 (one baby), type 47 (one), type 52A (one), and type not found (five); in the rectal swabs it was type 7/47 (one), type 47 (one), type 52 (one), type 52A (one), and type not found (two). On account of the variety of phage types in the first two outbreaks, and of the low incidence and sparsity of *Staph. pyogenes* in the rectal swabs in general, phage typing was not continued. The phage types determined in the first two outbreaks were not those commonly found in staphylococcal food-poisoning outbreaks—i.e., type 6/47 and type 42D (Allison, 1949).

Gale (1944) found large numbers of Group D streptococci with an unusually high tyrosine decarboxylase activity in the stools of cases in certain outbreaks of neonatal diarrhoea. A detailed examination was therefore made by Dr. P. M. F. Shattock and Miss M. E. Sharpe of streptococci isolated from the babies with epidemic diarrhoea of the newborn. Group D streptococci in small numbers were isolated from the rectal swabs of only three of these babies. Nine strains derived during this outbreak from these rectal swabs and from the intestinal contents of two other babies after death, together with two strains from the upper respiratory tract, were examined. They were found to be: *Str. faecalis*, 3; *Str. faecalis* var. *liquefaciens*, 3; *Str. faecalis* var. *zymogenes*, 3; unclassified, 2. These strains were found to be of several serological types. Their tyrosine decarboxylase activity varied from a high figure to *nil*. Scanty Group B streptococci were isolated from the rectal swabs of two other neonatal cases in this outbreak. *Clostridium* was found in only two of the 52 rectal swabs.

Thirty-four stools from cases of diarrhoea and vomiting were examined microscopically. Abundant bacteria were seen, varying numbers of epithelial cells, rarely more than a few leucocytes, and very occasionally a few red blood cells. No flagellate protozoa were observed. Stools from the 24 cases admitted to gastro-enteritis unit 2 (Group G) were examined for *Giardia lamblia*, each on two occasions, by Mr. L. G. C. Maslen, but none was found. The ether concentration method was used.

Blood was taken, at times varying from the second to the seventh day of illness, from the internal jugular vein of eight babies with *Bact. coli* D 433 in their rectal swabs. Six had severe and two moderate or mild attacks of diarrhoea and vomiting. Cultures were prepared in liquoid digest broth and incubated aerobically, anaerobically, and under CO_2 at 37° C. for 14 days. With the exception of two contaminated anaerobic cultures, no growth was found.

In summarizing the general bacteriological results of the rectal swabs it may therefore be said that no recognized pathogen was isolated, that *Proteus* and *Staph. pyogenes* (of phage types other than those of food-poisoning staphylococci) were each present in about one-third of the cases, that *Clostridium* was rarely found, and that Group D streptococci were not conspicuous in the outbreak of epidemic diarrhoea of the newborn. *Bact. coli* was the most frequently occurring organism, and, with the exception of a profuse growth of *Lactobacillus*, *Proteus*, or *Streptococcus* on some plates, it yielded the most abundant growth.

Serological and Other Investigations of Bact. coli Strains

Lovell (1937), working on the types of *Bact. coli* isolated from diseased calves, identified his strains by the precipitin reaction. Bray (1945), using the agglutination reaction suitable for the identification of the somatic antigen, isolated a particular serological type of *Bact. coli* var. *neapolitanum* from cases of infantile "summer diarrhoea." Kauffmann and his collaborators, using agglutination tests, identified the O or somatic, the H or flagellar, and the K antigens of the *Bact. coli* group: the K antigen may be of the L type (surface) or A or B types (capsular or surface), which are distinguished by their susceptibility to heat treatment. These workers were able to establish a diagnostic coli antigenic schema of O groups, subdivided into types and classified by their O, H, and K antigens. Giles and Sangster (1948) used their techniques for the identification of a serologically homogeneous strain of *Bact. coli* from over 90% of their cases of gastro-enteritis. Detailed information regarding the serology of the coli group may be found in the review of the subject by Kauffmann (1947) and the monographs by Vahlne (1945) and by Knipschildt (1945).

The methods used by these Scandinavian workers have been followed for the examination of *Bact. coli* strains isolated in this investigation. The first strains of *Bact. coli* to be investigated were derived from the outbreak of epidemic diarrhoea of the newborn (Group A). Primary blood-agar plates were inoculated with nasal, nasopharyngeal, throat, and rectal swabs taken from nine babies in the active stage of the disease, two in the convalescent stage, 11 baby contacts, and four babies at first suspected of epidemic diarrhoea of the newborn but later found to have ailments other than this; the intestinal contents of four babies who died from epidemic diarrhoea of the newborn were taken at necropsy and similarly plated. Colonies suggestive of *Bact. coli* were picked from all those

plates on which they were found, the number picked depending on the number of colonial forms present. Each strain was then tested for its fermentation reactions on a variety of "sugars," the production of indole, urease, and H_2S, utilization of citrate, Voges-Proskauer and methyl red reactions, liquefaction of gelatin, gas production at 44° C., and haemolysis (using the method described by Vahlne). In this way 178 strains of *Bact. coli* were isolated. The subsequent serological investigation of these strains will be described later.

For the preparation of sera, eight strains of *Bact. coli* isolated from active cases of epidemic diarrhoea of the newborn (Group A) were used. Six of these strains had been isolated from the rectal swabs of six babies, one from the nasopharynx of one of these babies, and one from a subcutaneous abscess of another of them. This abscess had formed at the site of a subcutaneous injection. These eight strains were chosen because in their biochemical reactions they showed some slight variation from one another and were representative of other strains found.

O sera were made in rabbits, using as antigen an overnight broth culture steamed for 2½ hours. K sera were made, using a living culture which had grown overnight on a thick 0.1% glucose-agar plate, a suspension of about 500 millions per ml. in quarter-strength Ringer solution being employed as inoculum. O and K sera were made from each of the eight strains. One of the rectal strains was motile, and from this an H serum was made using a formolized overnight broth culture. Thus, a total of 17 sera were prepared. Cross-agglutination and reciprocal-agglutination absorption reactions were carried out between these 17 sera and the eight strains of *Bact. coli* used for their production. From the results obtained it was obvious that five of the strains were serologically identical; of these, three had been isolated from rectal swabs and the fourth and fifth from the nasopharynx and rectal swab respectively of another baby.

This serological type is referred to as *Bact. coli* D 433. It is non-motile, therefore O and K sera only were used for its identification. It was tested with *Bact. coli* sera kindly supplied by Dr. G. Vahlne, and was found to be different from any of the 25 O groups of the diagnostic coli antigenic schema of Kauffmann, Knipschildt, and Vahlne. The organism is not capsulated, so that the A antigen was not considered. The presence of an L antigen could not be demonstrated, but a B antigen may be present, though more work is needed for the proof of this point. Dr. F. Kauffmann in a personal communication states that he believes *Bact. coli* D 433 has a surface antigen of the B type and that both the O and the B antigens differ from those of other strains in the schema. The strain of *Bact. coli* isolated by Giles and Sangster (1948) was tested and found to be identical with *Bact. coli* D 433.

The titre of the *Bact. coli* D 433 O serum was 1 in 6,400 and of the *Bact. coli* D 433 K serum 1 in 800. It was considered that these titres were high enough to show any differences between *Bact. coli* D 433 and related serological types which might subsequently be investigated. All the 178 strains already isolated in connexion with the outbreak of epidemic diarrhoea of the newborn (Group A) were then tested against each of the 17 sera. The results suggested that *Bact. coli* D 433 might be related to the outbreak in that it was isolated from the nine active cases examined, from the four cases at necropsy, and from three of 11 contacts; it was not isolated from the two convalescent cases of the disease or from the four cases other than epidemic diarrhoea of the newborn.

The *Bact. coli* D 433 O and K sera, already prepared with strains from cases of epidemic diarrhoea of the newborn, were used for the subsequent identification of *Bact. coli* D 433 among the sick babies and contacts and controls of Groups B–L. Material from these babies was plated on blood-agar. From all plates on which "coliform" colonies appeared four discrete colonies were tested with *Bact. coli* D 433 K serum by the slide-agglutination method. One agglutinable colony was then taken from each "positive" plate and its characteristics investigated. Without serological tests it was not possible to identify colonies of *Bact. coli* D 433 either on blood agar or on desoxycholate-citrate-agar plates. If *Bact. coli* D 433 colonies were overgrown with *Proteus* they were sometimes found to be inagglutinable by the slide method. In this event it was usual to test discrete colonies on duplicate primary plates of blood agar + 1 in 1,000 chloral hydrate; if these were not available, colonies subcultured on to this medium from the primary blood-agar plates were tested.

In all, 133 cultures of *Bact. coli* D 433 were investigated; they were derived from clinical cases of diarrhoea and vomiting and their contacts. All the strains were non-motile. All fermented lactose, glucose, maltose, mannitol, and sorbitol, with the production of acid and gas, after overnight incubation at 37° C. The fermentation of sucrose, salicin, and dulcitol was occasionally rather slower, but the majority of strains gave acid and gas in these "sugars" in four days. All strains were V.P.−, M.R.+, produced indole, failed to utilize citrate, gave acid and gas in MacConkey broth when grown at 44° C., and failed to liquefy gelatin or to produce H_2S. The large majority of the strains when grown on 10% horse-blood-agar plates showed no ring of haemolysis round well-isolated colonies, though there was always haemolysis in the area of confluent growth. Each strain was subjected to the haemolysis test; only six strains gave a positive result. All strains were agglutinated to titre by *Bact. coli* D 433 K and O sera. Representative strains from each group of babies investigated were used for absorption tests and completely removed all agglutinins to the homologous strain.

We have already stated that an anaerogenic strain of *Bact. coli* was isolated from a number of newly born babies accommodated in the maternity nurseries where over a year before epidemic diarrhoea of the newborn had occurred. This strain produced acid but no gas in lactose, glucose, maltose, mannitol, and sorbitol, failed to ferment sucrose and dulcitol, and gave variable reactions in salicin. The other biochemical reactions were the same as those of *Bact. coli* D 433. The O and K antigens of the two strains were identical, but the anaerogenic strain possessed in addition an H antigen and in this respect differed from *Bact. coli* D 433.

Four motile aerogenic strains of *Bact. coli* having the O and K antigens of *Bact. coli* D 433 were isolated during the investigation. These strains were derived from the rectal swabs of four babies, two of whom had mild attacks of diarrhoea and vomiting and were included in Group E and Group H respectively. The other two were healthy babies. The first of these was included in Group K (healthy controls) and the second was among the neonatal babies swabbed in the maternity nursery where epidemic diarrhoea of the newborn had occurred 14 months previously; their progress reports for 2½ weeks after swabbing showed that they remained free from diarrhoea and vomiting during this period. The biochemical reactions of these strains showed no constant difference from those of *Bact. coli* D 433, though two strains failed to ferment maltose in

24 hours but did so later. In view of their motility these strains have not been classed as *Bact. coli* D 433. It has not been possible to assess their significance, particularly as they have been so few in number.

Thirteen strains of *Bact. coli* isolated from calf scours were tested. The biochemical reactions of some strains were similar to those of *Bact. coli* D 433, but all the strains differed from it serologically.

Pathogenicity tests were carried out, using 18-hour broth cultures of *Bact. coli* strains, by intravenous and intraperitoneal inoculation, with and without mucin, of mice of various ages and by the intramuscular inoculation of guinea-pigs. One strain of *Bact. coli* D 433, two strains from calf scours, one strain from a subcutaneous abscess, and one strain from a healthy child were tested. All the strains were pathogenic to animals, but no marked difference in degree of pathogenicity could be detected between them.

Discussion

Among over a hundred cases of infantile diarrhoea and vomiting no recognized intestinal pathogen was detected and virus studies of four fatal cases yielded negative results. A serological type of *Bact. coli*, referred to as *Bact. coli* D 433, was first identified during an outbreak of epidemic diarrhoea of the newborn in a maternity unit. It was present in all of the nine babies available for examination during the active stage of the disease. The same serological type was subsequently isolated from all of 22 cases of diarrhoea and vomiting examined during two outbreaks in a mothers and babies' hostel and one outbreak in a residential nursery. The results thus showed a constant association between *Bact. coli* D 433 and cases of undoubted infective origin.

Clinically, the characteristic feature of the cases in these outbreaks was diarrhoea and vomiting, leading to dehydration. Parenteral infection at the onset was limited to one case of bronchopneumonia. The strain was also isolated from 21 (91%) out of 23 sick babies who developed diarrhoea and vomiting during in-patient treatment in a children's hospital. In this group only two of the babies showed any evidence of parenteral infection at the start of their attacks. The circumstances in this series suggested that some, if not all, of these intercurrent cases were of an infective type.

Lower association rates between clinical cases and *Bact. coli* D 433 were found among the routine admissions to two gastro-enteritis units. These units accept cases from a wide area on the recommendation of medical practitioners, and therefore admit babies with diarrhoea and vomiting of possibly varying aetiology. In the first unit, six (43%) of the 14 cases yielded the strain. The clinical history of five of these six babies suggested that the attacks were of an infective type. In the second and larger unit *Bact. coli* D 433 was found in only five (21%) of a series of 24 babies admitted with diarrhoea and vomiting. The strain was not detected among the 14 babies examined in a large residential nursery. Their attacks of diarrhoea and vomiting were insidious in onset, and 11 of them were mild in type. The series of cases was spread over a period of two months and appeared to be due to a rise in incidence of the diarrhoea and vomiting endemic in this nursery rather than to an outbreak of the disease: it differed, therefore, in this respect from the sharp outbreaks which were investigated among other infant communities. Among a control series of 208 babies *Bact. coli* D 433 was not found.

The majority of the babies in whom *Bact. coli* D 433 was present had severe attacks of diarrhoea and vomiting. The relatively large number of severe cases associated with the strain may have been due, however, to the selection of this type of case for investigation. An unselected series of cases might have shown a different incidence of the strain in relation to severity. *Bact. coli* D 433 was in fact found in some mild examples of the disease such as those of the second outbreak in the mothers and babies' hostel.

The distribution of *Bact. coli* D 433 was not closely confined to one area or to one season of the year. The strain was found in counties as widely separated as Derbyshire and Sussex, and was isolated during all seasons from the winter of 1947 to the summer of 1948. It was not restricted to one age group among the cases, for the strain was present in babies ranging in age from 10 days to 11 months. It is interesting to note that *Bact. coli* D 433 was present both in young babies with epidemic diarrhoea of the newborn and in older babies with infective diarrhoea and vomiting.

Consideration was given to the possibility that *Bact. coli* D 433 may have owed its existence in the stools to some common factor in the feeding of those babies from whom it was isolated. An analysis of the feeds which were being given at the time of swabbing and during the previous few days showed, however, that the babies had received a variety of preparations and several types of added sugar. A small number were fully or partially breast-fed. Similarly, the administration of chemotherapeutic drugs could not be held responsible for the appearance of the strain, since 42 of the 63 sick babies from whom it was isolated had not received this form of treatment.

A diarrhoeal condition is evidently not essential for the existence of *Bact. coli* D 433; this was shown by the fact that the strain was isolated from a number of adult and baby contacts who remained free from intestinal disturbance. The possibility that the serological type may result from alimentary-tract conditions pertaining to all diarrhoeal states seems to be ruled out by the fact that it was not found in a number of babies with watery diarrhoea. More difficult to determine is whether the strain, present in small numbers and therefore passing undetected in the stools of the normal infant, may grow out freely under particular intestinal conditions associated with only certain forms of diarrhoea. Before reaching a decision on this matter a readier method than slide agglutination will be required for the detection of small numbers of *Bact. coli* D 433 on culture plates.

Relapses are a common occurrence during the course of diarrhoea and vomiting. Five babies were admitted to gastro-enteritis units with mild or moderate diarrhoea and vomiting. While under treatment they developed severe relapses with dehydration. *Bact. coli* D 433 was not isolated from them during their initial attacks, but it was found in all of them during their relapses. It seems possible that the relapses were in fact attacks of infective diarrhoea and vomiting acquired within the unit and superimposed on some milder primary condition.

In the later stages of the work a *Bact. coli* strain closely related antigenically to *Bact. coli* D 433 was isolated from babies in the maternity nurseries in which epidemic diarrhoea of the newborn had occurred more than one year before. It differed from *Bact. coli* D 433 in the possession of an H antigen and in producing no gas in "sugars." Some of the babies from whom it was isolated suffered from a mild and transient diarrhoea, but they were evidently free from diarrhoea of the severe epidemic type. Four aerogenic motile strains having the O and K antigens of *Bact. coli* D 433 were isolated from four older babies, two with

diarrhoea and vomiting and two healthy. The significance of these related strains of *Bact. coli* cannot as yet be assessed, but further work may bring an answer to this problem.

Another and more important problem is the possible status of *Bact. coli* D 433, when confirmed by biochemical and serological test, as a causative agent of infective diarrhoea and vomiting. Its close association with clinical cases in certain outbreaks of diarrhoea and vomiting and its absence from control groups of babies suggest that it may play some part in the genesis of the disease, but further work is necessary before any definite conclusion can be reached. Possible lines of research are animal transmission experiments, pathogenicity and toxicity tests, laboratory investigation of the strain for further distinguishing characteristics, closer correlation between the clinical findings and the detection of the strain, and studies of possible dual virus and *Bact. coli* causation.

Summary

A clinical and bacteriological investigation of infantile diarrhoea and vomiting was carried out. The clinical material was drawn from one outbreak of epidemic diarrhoea of the newborn (Group A), two outbreaks of diarrhoea and vomiting in a mothers and babies' hostel (Groups B and C), one outbreak in a residential nursery (Group D), intercurrent cases among sick babies in hospital (Group E), two series of admissions to gastro-enteritis units (Groups F and G), and endemic diarrhoea and vomiting in a residential nursery (Group H).

No recognized intestinal pathogen was isolated, and virus investigation of fatal cases yielded negative results.

Bact. coli sera, prepared from strains isolated from cases of Group A, led to the identification of a particular serological type, referred to as *Bact. coli* D 433. It was isolated from all nine cases examined during life in this outbreak.

The same sera were subsequently used for the identification of *Bact. coli* D 433 among the other groups of babies studied. It was isolated from all 22 cases (100%) of Groups B, C, and D, from 21 (91%) of the 23 cases in Group E, from 6 (43%) of the 14 cases in Group F, from only 5 (21%) of the 24 cases in Group G, and from none of the 14 cases in Group H.

Bact. coli D 433 was not isolated from any of the 208 babies of the control groups.

Five babies with mild or moderate diarrhoea and vomiting has severe relapses while in gastro-enteritis units. *Bact. coli* D 433 was not isolated from them during the initial attacks, but was present during the relapses.

Bact. coli D 433 was isolated from cases in seven counties and during all seasons of the year. The youngest baby in whom it was found was aged 10 days and the oldest 11 months.

Bact. coli D 433 was isolated from four of 84 adult contacts and from nine of 34 baby contacts examined in connexion with Groups A–E.

Bact. coli D 433 was not isolated from rectal swabs taken three to six months later from 82 infant occupants of nurseries and wards in which cases of diarrhoea and vomiting (Groups A–E) had been investigated. Fifty-one newborn babies, occupying the maternity nurseries in which epidemic diarrhoea of the newborn (Group A) had occurred, were swabbed more than a year after the outbreak. From 21 of them an anaerogenic motile *Bact. coli* strain was isolated which was closely related antigenically to *Bact. coli* D 433. Ten of these babies suffered from a mild diarrhoea the significance of which is at present undetermined.

Whether the serological type of *Bact. coli* has any aetiological significance in diarrhoea and vomiting is undecided. Lines for further research on this matter are indicated in the discussion.

We wish to acknowledge our thanks and indebtedness to the following: Dr. R. Cruickshank and Professor A. A. Moncrieff for their encouragement and advice; the Medical Committee of the Hospital for Sick Children, Great Ormond Street, London, for facilities for research in the wards and laboratories, and Dr. B. E. Schlesinger for his interest in the work; Dr. R. G. Cooke for facilities to make investigations in the Derby City Hospital; Dr. S. Dundon and Dr. R. E. Glennie for voluntary and invaluable service in the gastro-enteritis unit for neonatal diarrhoea; Mrs. W. S. Willett (working for the Public Health Laboratory Service) for the preparation of the *Bact. coli* sera and for much other bacteriological work during the early stages of the investigation; Dr. G. R. Osborn and Dr. M. Lécutier for permission to include their post-mortem findings; the medical officers of health of the areas in which investigations were made; the medical superintendents, medical officers, matrons, sisters, and nurses of the hospitals, nurseries, and welfare clinics concerned.

WHAT IS SOCIAL MEDICINE?*

BY

W. HOBSON, M.D., B.Sc., D.P.H.

Professor of Social and Industrial Medicine, Sheffield University

It is usually assumed that the expression "social medicine" is of relatively recent origin. Dr. René Sand (1948) has shown, however, that it was used exactly 100 years ago by Dr. Jules Guérin, writing in the *Gazette Médicale de Paris*. The idea of social medicine therefore is certainly not new. The only new thing about it is the reawakening of thought which realizes that here is something of fundamental importance that has been forgotten in certain circles.

If, in the past, clinicians have forgotten the importance of the environment in determining disease, hygienists have perhaps been too limited in their outlook and interpretation. Social medicine attempts to link together clinical medicine and preventive medicine in the hope of benefit to both. It is my purpose to try to illustrate the existence of a common ground between the two.

If we are to understand fully the meaning of and need for social medicine it is necessary to trace briefly the history of medicine as a whole and its relation to other branches of human activity.

To the Greeks medicine meant the art of healing; it achieved importance because of the necessity for curing a sick person of disease. The emphasis was therefore on the treatment of disease, and little or nothing was known of aetiology. Preventive medicine was certainly studied by Hippocrates, and his writings are full of sound reasoning concerning the spread of epidemics. Preventive medicine, however, could make no real advance until the basic sciences of physiology and bacteriology had been developed. Throughout the Middle Ages no advancement was made in

*A paper read to the West of England Branch of the Society of Medical Officers of Health at Bristol on Nov. 20, 1948.

our knowledge of aetiology, and treatment was largely empirical and often associated with magical and ritualistic rites. The Greeks also developed the idea of health not merely as absence of disease but as something to be cultivated.

The word hygiene, meaning "wholeness of body," is still in use to-day, and is associated with the idea of the production of a greater functional reserve against the encroachment of adverse influences by a discipline of clean and vigorous living. This theme of positive health is well illustrated by the words of William Morris: "First of all I claim good health; to feel mere life is a pleasure; to enjoy the moving of one's limbs and exercising one's bodily powers; to play as it were with sun and wind and rain; to rejoice in satisfying the due bodily appetites of the human animal without fear of degradation or sense of wrong-doing: yes, the wherewithal to be well formed, straight limbed, straightly knit, and expressive of countenance."

England was the first country in the world to control epidemic disease by the sanitary idea. Advancement in this idea did not of necessity depend upon the knowledge of causation of disease; indeed, the decreases in epidemic disease began before the germ theory of disease was established as a scientific doctrine.

Public Health

The Magna Charta of Public Health was passed in 1875, but for many years after that Sir James Creighton was disputing the germ theory of disease, and yet William Budd, working in this City of Bristol, had already shown the practical way in which excremental diseases were spread. Sanitary science is now a well-established technique, and as such it has its obvious social uses. It should not be taken for granted that it is any less necessary or less important than it was a century ago. It was perhaps unfortunate that the practice of public health was largely divorced from the practice of clinical medicine; indeed, it has been the fashion for the consulting physician to regard his brethren in the field of public health as belonging rather to another and inferior world.

The general practitioner, too, has tended to adopt a critically hostile attitude to the medical officer of health, and he has often resented an intrusion into the field of curative medicine. Certainly there has not always in the past been that happy liaison between the two which is to the best interests of the community. The public health services were saddled with the heavy responsibility of administering the municipal hospitals—a responsibility which was thrust upon them because the public health service was the only administrative machine in existence capable of dealing with it. It never was the function of a medical officer of health to enter this realm of curative medicine, and the recent steps taken to put these services under a separate authority are logical and necessary.

Side by side with the study of the environmental factors which affect health there was simultaneously a concentration of study on the disease processes in the sick individual. Diagnosis, which had formerly relied entirely upon the skill and experience of the physician at the bedside, became more and more dependent upon the intricacies of biochemical investigation, radiographic analysis, and the like, and the pathology of internal disease developed *pari passu* with the use of the microscope and the advancement in histological techniques. The era of internal medicine had arrived. Almost the whole of the resources of clinical medicine as practised in hospital were centred upon diagnosis and the removal of the disease process in the individual, and little attention was paid to the study of man in his environment.

This is the point of view which has permeated the teaching of medicine in many of our universities and medical schools. When he first qualified the medical student had received little or no training in the conduct of general practice. He soon learnt by bitter experience that to attach precise labels to disease was often difficult and impossible with his limited facilities. He discovered also that man is a social animal, and many of the disease processes he was called upon to control had roots in social sources, in particular that of poverty and all that is associated with it—bad housing, overcrowding, unemployment, and inadequate food.

Adverse Social Factors

To-day we realize that disease processes can be initiated not only by adverse factors in the purely physical environment but also by adverse factors in the social environment. With the growth of civilization and urbanization the technicalities of life have become more and more complicated and increasingly difficult to understand. The factors which make for a healthy social environment are becoming more difficult to obtain. A happy family circle, a full and adjusted community life at work and at play, a sense of purpose and responsibility in the world—these are of vital importance to social well-being. In the troubled times in which we live it is small wonder that the psychosomatic diseases such as duodenal ulcer and angina pectoris have increased in prevalence; and there are other pointers to psychosomatic imbalance, such as the increased urge for tobacco and the rise in juvenile delinquency.

It is also important to realize that diseases conditioned by an adverse environment have often inevitable social implications and repercussions in themselves. Tuberculosis, venereal disease, and many mental ills are typical and outstanding examples of those conditions in which the individual has in turn a responsibility to the community.

The family physician has always been aware of these various factors in the physical and social environment which affect the health of his patients, and he is equally aware that these factors are of profound importance in determining health or disease. Unfortunately, as an individual he is not always in a position to correct them, as the causes are often dependent upon the social framework and way of life of the community. There are, nevertheless, many factors in the environment which it is in our power to control, particularly by communal action. They come into the realm not only of preventive medicine but also that of curative medicine.

When we consider the effect of environmental factors upon health we find there is no hard-and-fast line between prevention and cure. The use of the term "preventive medicine" in this sense is therefore limited in its scope: the term "corrective" is perhaps more suitable. In America, according to Smillie, the term "preventive medicine" has an even more limited application. It is used to describe those activities in the prevention of disease which are the direct responsibility of the individual, and "public health" serves to denote those factors which are a responsibility of the community. However we define these terms it is clear that the physician in practice has an obligation to his patient and to the community to prevent illness and to promote family and communal health, and for that reason full diagnosis and adequate treatment are impossible without a knowledge of the social and economic factors which influence the life of the patient.

"Internal" and "External" Medicine

One thing is clear: the term "medicine" as used in its widest sense to-day is no longer limited to the art of healing. It includes the prevention and treatment of disease, and takes within its compass the study of the basic sciences of anatomy, physiology, and pathology as well as the healing arts of clinical medicine and surgery. It also includes within its scope the factors which promote health. There is no sharp dividing-line between health and disease—the one merges imperceptibly into the other; and I must stress the point that there can never be watertight compartments in medicine. There is a need for stressing the importance of environment in medicine, because in the teaching schools and in hospital practice this has often been forgotten. We can call this "external medicine."

In what way does "internal medicine" differ from external medicine? Internal medicine has for its background the study of the internal anatomy and physiology of the individual and the elucidation of the changes which take place in disease and their internal causes. It is concerned with the diagnosis of the disease condition and with the treatment of disease by the correction of the deranged mechanisms of the body, whenever possible. External medicine, on the other hand, has for its background the study of social structure and social pathology; it is concerned with the ultimate aetiology of disease and with those factors which promote health. It aims at the control of these factors both by individual and by communal action.

So far as research and investigation are concerned we can see two lines of development. The high-power research of the laboratory has centred largely upon internal medicine, mainly because the immediate results have been of practical value to the patient. But original research and investigation in external medicine, apart from epidemiology, have been haphazard and have lacked organization and co-ordination. With a few exceptions, what has been done has usually been carried out by individuals working alone in the course of busy routine work. But research in external medicine more than in any other branch requires team-work, organization, the use of statistical method, and survey technique. In the past undoubtedly valuable contributions have been made by medical officers of health; but as their time became more and more absorbed with routine work so their opportunities became less.

The result is that our knowledge of disease processes in the body and our advances in diagnostic technique have outgrown our knowledge of aetiology.

The practitioner of medicine must be a complete doctor; he must study and consider all factors affecting health, internal and external. Sir William Osler, one of our greatest clinicians and a prolific writer on internal medicine, was also a great exponent of the value of external medicine.

Definition of Social Medicine

With these ideas in our minds we are now in a position to give a definition of social medicine and to demonstrate its activities.

Social medicine is the study of those environmental factors which affect health, and the application of that study to the benefit of man. It has two main applications: (1) The use of this knowledge for the benefit of the individual both in health and in disease: this is a responsibility not only of the physician and surgeon but of each individual. (2) The use of this knowledge on a community basis: this is a responsibility of the community and has been known in the past as "public health" or "State medicine."

The term "environment" is used here in its very widest sense, to include not only the physical and social environment but also the study of heredity and genetics in their effect upon human health; and by the term "health" is implied "optimum health," and not just the absence of disease. Clearly we cannot be limited in our conception of the communal aspects of this branch of medicine.

From what has been said it is not possible to separate preventive from curative and individual from communal medicine. It may be asked why it has been necessary to reintroduce the term "social medicine" at all. I think the answer lies in the fact that the older terms "public health" and "preventive medicine" are too limited in their scope to define adequately the branch of medicine which I have described and which has definite claims to be regarded as a distinct branch. It also indicates the importance of the social environment as distinct from the purely physical environment. Unless we take into account all factors affecting health, our efforts to improve social evils may cause more harm than good. Thus Dr. Mannheim (1948) has shown that in Cambridge there is a much higher rate of juvenile delinquency on the new housing estates, just as Dr. M'Gonigle at Stockton-on-Tees found a higher death rate in a population which had been moved from a slum area to a new housing estate. Rehousing in itself is no cure for social evils.

Clearly there are many factors not mentioned in the Public Health Acts which affect health, and it is difficult to envisage any field of human activity or endeavour that does not have its repercussions upon the health of the individual—agriculture, the Road Traffic Acts, the employment of labour, town planning, crime, finance, sport, and even politics. It is this common interest which brings social medicine in relation to so many phases of human activity.

Mortality Statistics

One of the basic sciences of social medicine is that of social pathology, just as the basic science of clinical medicine is human pathology. Its function is to study the disorders and ills dependent upon a communal life. The idea, however, is certainly not new. One of the greatest accounts of social pathology was that written by Edwin Chadwick (1842). This was, however, largely concerned with the physical environment. Much of the information on the adverse effects of environment can be ascertained from the study of mortality statistics, first instituted by John Graunt and later developed by William Farr. Our information on communal mortality is contained in the Registrar-General's Reports. Perhaps the most important of all these is the Decennial Supplement on Occupational Mortality for 1931. Although this document was not published until 1938 it constitutes the most complete account in any country of mortality analysed by occupation and social class. The technique of the analysis of mortality statistics has been described by John Ryle (1948) as the "social post-mortem."

It is easy to arrive at erroneous conclusions from a study of mortality statistics. The Registrar-General has made every endeavour to eliminate these from the purely statistical point of view. He is able, for example, to measure the effect of an ageing population and to counteract this effect by the use of special devices: this is particularly important in such diseases as cancer and heart disease. He is not, however, able to measure changes in the fashions and trends of diagnosis. We know that there have been considerable changes and inaccuracies in diagnosis in recording the cause of deaths. This may make considerable differences in such diseases as bronchogenic carcinoma and

the leukaemias. An interesting example is seen in the changing trend of diagnosis between nephritis and essential hypertension, which has recently been analysed in cotton-workers by Platt.

The value of mortality statistics lies not so much in their relative accuracy as in the fact that they are pointers to lines of more detailed study and research, lines of study which should give vitally important information on the causation of disease. It is clear that for their correct interpretation one must have some knowledge of disease processes in the body. There is no doubt that here is common ground for social pathology and internal pathology, and the one can make good the deficiencies of the other.

The morbid anatomist is too often apt to regard his material as characteristic of the population as a whole. Usually, however, his material is highly selective and is based on a very small sample of the population. On the other hand, the information which is gleaned by the social pathologist very often includes the whole population. The wise pathologist will not limit his activities to the field of morbid anatomy. He will combine the studies of experimental and social pathology and endeavour to correlate the findings of these techniques. But the use of such methods is still in its infancy; that is why I look to the future to see the increasing use of morbidity and mortality statistics as research tools of the social pathologist.

Infant Mortality

If we attempt to analyse mortality we find that it is greatest at the extremes of life. In infancy and old age the individual is less adapted to withstand adverse environmental factors. The infant mortality rate has often been used as an index of the healthiness of a community, and there is a considerable differential class mortality, the mortality rate being considerably higher in the lower social groups. This information has been analysed in detail by Titmuss, who has shown that this differential class mortality, contrary to what is usually assumed, is, if anything, becoming more pronounced. I would draw attention to the fact, however, that mortality in the second year of life is probably a more sensitive index of environmental factors. Thus the mortality rate from measles during the second year of life is 19 times greater in the lowest social class than in the highest.

I would here like to draw attention to an interesting feature of infant mortality in relation to the occupation of the father. When we consider those occupations which are connected with the highest infant mortality, are we right in assuming that the social way of life entailed by those particular occupations is responsible for the high loss of infant life, or are there genetic influences at work? Also, are there sufficient numbers from which to draw any significant conclusion?

As one would expect, there is a very high mortality amongst the infants of labourers, costermongers, and similar groups. Three occupations, however, show a high infant mortality where one would not expect it to occur. These occupations are sugar-confectionery makers, retailers of sugar confectionery, and salesmen of sugar confectionery. I shall leave you to decide whether there is any real significance in the association of a high infant mortality with employment in the sugar confectionery trade.

There are, of course, not only diseases of poverty; there are also diseases of affluence. Thus gout, diabetes, and particularly cirrhosis of the liver show a greater mortality in the higher social classes, and in publicans in particular. It is interesting to note that a considerable fall in mortality in these diseases occurred during the war, a fall which was not shared by our neighbours in America. And what of the diseases of worry, the so-called psychosomatic affections, of which duodenal ulcer and angina are important examples? Surely there is some significance in the observation that the mortality has increased during the last few years and that it is greatest in the higher social classes?

I shall not attempt to discuss all the possibilities envisaged by these observations, but hope that they will stimulate others to search this fascinating publication, the Decennial Supplement on Occupational Mortality, for further information, and perhaps even to pursue their own inquiries into the aetiological relationships suggested by this technique of the "social post-mortem." Personally, whenever I pick up some occupational mortality supplement I never fail to find something new and exciting.

Duties of Medical Officer of Health

In 1925 the Ministry of Health issued a memorandum on the duties of the medical officer of health, and in it appears this sentence: "He should endeavour to acquire an accurate knowledge of the influences, social, environmental, and industrial, which may operate prejudicially to health in the area."

So far as the study of the occupational influence is concerned it remains virtually an unexplored field to the medical officer of health. He has therefore a great part to play in the development of this idea, and a fresh sphere of opportunity awaits him. The loss of the millstone of hospital administration can only be to his ultimate advantage, for in that way he is left free to investigate the environmental factors which affect health. The opportunities will present themselves, but to make full use of them he must go to the homes of the people and become more closely associated with the activities of clinical medicine. The formation of practitioner health centres should provide a great opportunity for him in this respect. The only way to obtain the final answer on the aetiology of many disease conditions is to study man in his environment. This is no new idea; it was expressed by Ramazzini in 1705 in words which might be applicable to-day: "For my own share I have done what I was able to do and thought it no indecency to step sometimes into the meaner sort of houses, especially now that almost all physic is reduced to mechanism and the schools sound of nothing so much as an automaton or machine of the body, the shops and houses of tradesmen are the only schools in which we can find any satisfactory knowledge of these matters."

Two important and stimulating addresses on the importance of this idea have recently been given—the first by Professor Parry (1948) in his Presidential Address to the Society of Medical Officers of Health, and the second in a broadcast in the Third Programme by Dr. Cohen (1948); perhaps Professor Parry will forgive me if I make a comparison between the two. Professor Parry has indicated how important it is that the medical officer of health of the future should become more clinically minded and have opportunities for visiting the homes of the people. Dr. Cohen, on the other hand, has shown how meagre is our information on the social sciences, how little we really know of the way people live, and the need for a science of society. There is a woeful lack of data on which to base a scientific approach to the planning of health services and an absence of any kind of research organization in public health departments.

One would have thought that such organizations were essential before we could even begin to find the answers

to some of our practical problems. I hope that in the future the Minister of Health will make some constructive proposals enabling public health departments to set up machinery for sociological investigation, for this is urgently needed to answer some of our immediate practical problems, quite apart from the more fundamental research into aetiology, which must be carried on by university departments of social medicine. Nor must we be cheese-paring in our demands: this type of research requires teams whose sole function is research and whose time is not burdened with routine duties.

Statistical Method

It is clear that false conclusions and deductions can arise from the observations of one man alone, and it was not until the statistical method was applied to the measurements of morbidity and mortality that any real advance was made. Unfortunately, similar mistakes are perpetrated to-day, and medical men in particular are very prone to generalize from results of their own often limited experience. That is why I regard the use of the statistical method of the utmost importance in the study of social medicine.

In the words of Greenwood: "The knowledge which a great physician has of the body and of the mind is neither meagre nor unsatisfactory, but physicians great or small cannot assess group experience without resort to a calculus of groups which must be statistical." One has only to glance through the sections on aetiology in some of the earlier textbooks of medicine to realize the importance of this statement. There are mistakes the origin of which can be traced back to the limited observations of one man. Such mistakes are copied from textbook to textbook, and once they have appeared in print they are more than difficult to eradicate, and even to-day some are still retained. The recorded observations on normal ranges of physiological variations in groups of human beings are also in a very chaotic state, and, apart from Price-Jones's research into the size of the red cell, there has been very little real work done on a statistical conception of normality. The Grant study at Harvard is an attempt to remedy this. When we look for an organized science of aetiological relationships we can see that it is heavy with hypothesis and dismal with uncorrelated observations. Practical success in the prevention of disease depends upon advances in our understanding of causation. As Seiglitz has pointed out, there are predisposing, provoking, and perpetuating factors in disease, all of which come under the heading pathogenesis, and there is rarely one single aetiological factor. I am certain that it is fundamentally wrong to think of a single cause in aetiology. Tuberculosis provides a very good case in point. It may be caused by the tubercle bacillus, but, in terms of practical politics, genetic, nutritional, and environmental factors are of considerable importance in determining the onset of disease. How else can we explain the fact that some individuals can remain perfectly healthy despite heavy and repeated exposure to the tubercle bacillus and yet others require only a minimal exposure to produce a widespread and extensive disease process? Very often the predisposing and perpetuating factors are of greater importance than the provoking factors.

Of all diseases which require detailed investigation none is more important than tuberculosis. Here is a disease of which we know the predisposing, provoking, and perpetuating factors in its causation, and yet it remains the most important cause of death in young people. In females in this country aged 15–20 it still accounts for 40% of deaths. There can be no more important study than the social medicine of tuberculosis.

So far I have confined myself to a study of mortality; that does not mean that the causes of ill-health are not important. In the words of Dickens: "It concerns a man more to know the risk of the fifty illnesses that may throw him on his back than the possible date of the one death that must come." It is over fifty years since Sir John Simon recognized the importance of information on morbidity statistics and advocated their use. We still have no organized means of obtaining such information.

Important Aspects

This conception of social medicine would not be complete if it did not indicate in some degree the emphasis to be placed on its various aspects. There are those who would place this emphasis on its application to the benefit of the patient in hospital, others on health and its communal aspects. John Ryle, himself a clinician of considerable experience and the first professor of social medicine in this country, has elaborated the importance of social medicine in its clinical application. He has nevertheless indicated that the aspects associated with the community and its relation to health are possibly of even greater importance. It is clear that our conception of social medicine must include within its scope the realm of preventive medicine, public health, occupational medicine, and the application of those humanitarian principles so long practised by the good family physician.

There is no doubt that the occupational environment is of supreme importance, but it seems to me that the relative importance of industrial toxicology in the causation of ill-health and death has been grossly exaggerated. It is fascinating and exciting to read about beryllium lung and manganese pneumonitis, but disease arising from such specific poisons is extremely rare compared with the common diseases from which men suffer and die. Many occupations show a high mortality rate because of the social way of life necessitated by those occupations. This is proved by the fact that in a great many occupations the high mortality rate of the men is shared by the wives who are subject to the hazards of the same social environment but do not share the specific occupational hazards. There are of course occupations which have high mortality because they attract men of poor physique—for example, tailoring, printing, and the boot and shoe industry.

Conclusion

In a free society our aims must be to provide a healthy environment and to ensure that all possible measures are taken to secure freedom from disease. Each individual must be left free to develop according to his own needs and requirements. The idea that there should be any dragooning into health savours to me of the Nazi doctrine: hard physical exercise is not the only way to achieve optimum health. That is why I am always a little suspicious of those individuals who talk about positive health.

I regard social medicine as a philosophy which should permeate all branches of medicine, for its implications cannot be divorced from any branch of medical learning. It is a branch of medicine also which provides a connecting-link with the wider humanities. In the teaching of medicine the accumulation of facts has been pursued, to the neglect of the study of man in his environment. The liberal and intellectual structure of medicine and the humanism of medicine are often lost in a welter of technical detail. It is well to remember that the great pioneers of social medicine were men of liberal education and wide outside interests. They were interested in men as part of humanity.

If I were asked to define social medicine concisely I should answer: "The study of man within his environment, to give him life and to give it more abundantly."

THE AGE OF THE MENARCHE

BY

DAGMAR C. WILSON, M.D., M.R.C.P., F.R.C.O.G. D.P.H.

AND

IAN SUTHERLAND, M.A., D.Phil.

(From the Institute of Social Medicine, Oxford)

During the past century there has been a general tendency for European children and adolescents to grow with increasing rapidity, so that at a given age they are now taller and heavier than children of 50 years ago. This effect is also found in the more privileged classes compared with the less privileged, and has been ascribed to better nutrition (Morant, 1939). Studies of London school-children reflect a similar secular change in growth (Daley, 1948). The possibility that earlier sexual maturity may be associated with this accelerated growth in stature and weight is a matter of some social importance and has led to the present inquiry.

It is generally accepted that the development of sexual maturity is influenced both by heredity and environment and, more directly, by the action of pituitary hormones on the thyroid gland and gonads. H. Hogben, J. A. H. Waterhouse, and L. Hogben (1948), in a noteworthy contribution to the study of puberty, have discussed the salient features concerned in the process of full development. Ellis (1948) has shown that when comparing growth and nutrition in groups of boys and girls the stage of sexual maturity of the individuals concerned is almost as important as their chronological age; he has suggested a simple clinical grading for the use of school medical officers.

The onset of menstruation, now usually referred to as the menarche, represents to the individual girl a very definite point in time, which can be accurately determined retrospectively within a few years of its occurrence. No other aspect of sexual maturation, whether in girls or in boys, is so striking. Thus, although the onset of menstrual periods is only one aspect of a complex developmental process, information regarding it can be obtained quickly and reliably. For these reasons the present study is confined to sexual maturation as exemplified by the age of the menarche.

Observations in many different countries show that groups differ in the average age of the menarche. A number of associations between the age of onset of menstruation and environmental influences have been stressed by several investigators. (1) It has been stated that town girls on an average menstruate earlier than country girls. (2) Associations with height and weight have been demonstrated. (3) It has been asserted that girls nowadays are menstruating on an average at an earlier age than did their mothers (Kennedy, 1933; Pryor, 1936; Michelson, 1944). The present investigation was planned to consider afresh these three suggestions.

Data

Data were collected from nine secondary girls' schools of which three are in Oxford City and the other six in Oxfordshire. The schools draw children from a variety of social and economic environments. The information included the present ages, heights, and weights of the children, together with a record of whether their menstrual periods had started, and, if so, of their age at the time of onset. In order to be sure that the samples were representative of the geographical areas served by the schools children were included only if they had been resident in the area for at least three years preceding the menarche or the date of the inquiry, whichever occurred earlier. At one city school the information was available only for those whose periods had already started. In all, records were analysed for 1,338 girls between the ages of 10 and 19—572 were from city schools and 766 from country schools. Of the total, 604 had not started menstruating when the inquiry was made.

City and Country Schools

The age of onset of menstruation ranged in individual girls from 9 to 18 years. The average age of the menarche among the children who had attained it was 13.23 years. In the three city schools the figure was 13.4 years and in the six country schools 13.09 years. However, in each school a substantial proportion of the girls had not started menstruating, and this fact makes the average ages quoted above dependent upon the age distribution of the children in the various schools. Schools with a higher proportion of older girls will naturally return a higher mean age at the menarche among those whose periods have started. This effect is shown in Table I.

TABLE I.—*Age of the Menarche in City and Country Schools*

	Average Age of Menarche	Average Age of All Children
City schools	13·40 years	14·03* years
Country schools	13·09 ,,	13·70 ,,
All schools	13·23 ,,	13·83 ,,

* Two schools only.

It is evident that the apparently lower age of the menarche in country schools may express no more than the younger average age of the children at those schools. The point was tested explicitly in the following manner. It is possible from the data to calculate for each birth anniversary the percentage of girls who have started menstruating by that age. The information for *every* girl who has passed the particular birth anniversary, whatever her present age, may be used to contribute to the calculation of this percentage. Table II shows

TABLE II.—*Percentages of Children who have Attained the Menarche by Various Ages in City and Country Schools*

Age	2 City Schools	6 Country Schools
9	0·0	0·0
10	0·2	0·0

Metric equivalents: 1 inch = 2·54 cm.; 1 lb. = 454 g.

any suggestion of a greater spread in the age of the menarche among one group of children than among the other. There is thus no apparent difference between the children from town and country in respect of age at the menarche.

Height and Weight

Table III gives the mean heights and weights of all the children studied according to their present age and their age at the menarche. The data for those children whose periods had not started are analysed according to their present age.

The most striking feature of the table is the considerably greater mean heights and weights among those who have menstruated compared with those of the same age who have not. Where weights alone are concerned the frequent plumpness of girls at this phase of life has long been a familiar observation. For children of 11 or 12 the difference in average height is about 3 in. (7.5 cm.) and in weight about 25 lb. (11.3 kg.). For children of 14 or 15 the difference in mean height is about 1¼ in. (3.75 cm.) and in weight about 17 lb. (7.7 kg.).

The columns of the table give some indication of the way in which present height and weight depend upon the interval since the menstrual periods started. There seems to be little or no variation in present height according to the interval since the menarche. There is a slight tendency among the younger girls for those who first menstruated recently to have lower weights than girls of the same age who first menstruated earlier. It is quite evident, however, from the figures that growth is much slower after the menarche, and that there must be a considerable spurt in growth shortly before or around the time of onset of the menstrual periods.

Mothers and Daughters

At one of the city schools it was possible to arrange an approach to the mothers of the girls who had already menstruated, and to obtain, in confidence, information regarding the age of the mother at her menarche. The mothers of 54 girls were involved. The mothers of two were dead, and it was not possible to get in touch with the mothers of three others. A brief explanatory questionary was posted by the school medical officer to the mothers of the remaining 49 girls and replies were received from the mothers of 41. Mother and daughter were given a common code number by the school authorities and so in each instance the difference between the ages at menarche could be determined. In this way genetic differences were allowed for to some extent.

Table IV shows the distribution of the differences in ages at the menarche. In 16 instances the daughter was older than the mother; in 16 instances the mother was older than the daughter; and in nine instances the ages at the previous birthday were identical. There is no evidence from this admittedly small sample of any decrease in average age at the menarche.

TABLE IV.—*Age of Mother at the Menarche Minus Age of Daughter at the Menarche for 41 Daughters (39 Mothers)*

Difference Between Ages at Birthday Previous to the Menarche (Mother minus Daughter)	No. of Instances

−3 ,,	1	
−2 ,,	7	16
−1 year	7	
0	9	
1 ,,	8	
2 years	6	16
3 ,,	2	

Discussion

The negative findings in the first and third parts of this inquiry are not necessarily inconsistent with earlier findings. The association between height and weight and the age of the menarche, which appears so clearly from the figures presented here, suggests that nutrition may be an important factor in sexual development, and the adequacy of nutrition could well differ as between town and country or between one generation and the next. In this instance it is doubtful

if considerable differences in nutrition do occur between the children in the various schools, where milk and meals are provided, or in their homes, where the dietary is both uniform and adequate as a result of equitable rationing during the past nine years. The mothers who were approached regarding their own age at the menarche were drawn from favoured social groups, and it is unlikely that the mothers' nutrition differed greatly from that of their daughters. It is unfortunate that the planning of a similar inquiry among mothers in poorer homes would probably be hampered by prejudices associated with the subject.

The figures in Table III confirm the conclusion of Ellis (1948) that the stage of sexual maturity is as important in assessing growth as is chronological age. It is noteworthy that no entry relating to the age of the menarche is at present included in the new school medical record card of the Ministry of Education. If the physical growth of girls is to be adequately assessed this omission will need to be remedied.

Shuttleworth (1937) presents individual growth curves of 10 girls who first menstruated between 10 years 7 months and 11 years 3 months, and of 10 girls with menarche between 14 years 5 months and 15 years 2 months. The first group were on the average taller during the period from 8½ to 12 years of age than those in whom the menarche occurred later. There was a rapid decrease in rate of growth in stature after the menarche. Those whose menarche was later continued to grow after the girls in the earlier group had practically ceased and in the end were taller. Our findings do not confirm this last observation: Table V summarizes the figures of Table III for the 47 girls aged 17 and 18. There is no consistent tendency for those whose menarche was later to be either taller or heavier than those who first menstruated earlier.

TABLE V.—*Mean Heights and Weights of Girls aged 17 and 18 According to Age of the Menarche*

Age of the Menarche	No. of Girls	Mean Height	Mean Weight
Under 13 years ..	10	64·4 in.	125·4 lb.
13–14 ,, ..	13	64·6 in.	135·7 lb.
14–15 ,, ..	13	64·3 in.	119·9 lb.
15 years and over ..	11	65·1 in.	125·4 lb.
All ages	47	64·6 in.	126·8 lb.

Conclusions

Data concerning the age of the menarche were obtained from 1,338 girls (604 of whom had not yet started their periods), between the ages of 10 and 19, attending three secondary schools in Oxford City and six in Oxfordshire. These schools cater for children from a variety of social and economic environments.

1. No differences in the age of onset of menstrual periods could be detected between children attending the town and country schools. The median age (that at which half of the girls had started menstruating) was 13.6 years. The age ranged in individuals from 9 to 18 years.

2. Girls who have not started menstruating are considerably shorter and lighter than their fellows of the same age whose periods have started. On the other hand, there is little difference in the mean heights and weights of the latter groups when subdivided according to the interval since the menarche. It is concluded that there must be a considerable spurt in growth before or around the age of menarche.

3. The close relation with height and weight means that information on the age of menarche is essential for the adequate assessment of physical growth in adolescent girls. As yet no provision is made for this information on the Ministry of Education's new school medical record card. This omission should clearly be made good.

4. A small number of mothers of a more favoured social group were compared with their children in respect of the age of menarche. There was no apparent tendency for the children to start menstruating at an earlier age.

5. It is suggested that the negative findings (1) and (4), which fail to confirm the work of earlier investigators, may arise from the comparable nutritional status before or during adolescence, in this country, of the groups involved.

6. There is no evidence that the height and weight of girls aged 17 and 18 is in any way related to the age at which they first menstruated.

We are indebted to the educational and medical authorities and the teaching staffs of nine schools in the City and County of Oxford, to Dr. Isabelle Little in particular, and to the mothers of the girls for their help in obtaining the necessary data.

OBSERVATIONS ON THE TREATMENT OF INFANTILE GASTRO-ENTERITIS

BY

C. ZAHRA NEUMANN, M.D., D.C.H., M.R.C.P.
(*From the Royal Malta University*)

The aetiology of infantile gastro-enteritis is still far from clearly understood. In a proportion of cases met with in Malta, especially in our hot summers, the disease is almost certainly of infective origin, but the nature of the causative organisms is a matter of acute controversy, as it has been impossible to incriminate any specific agent except in some cases belonging to the dysenteric, enteric, and salmonella group of diseases. Bacteriological examination of the stool of healthy and sick babies has disclosed no qualitative differences; indeed, some paediatricians have held that gastro-enteritis was not provoked by any specific organism but that it originated from the invasion of territory normally sterile, such as the upper reaches of the small intestine (Moro, 1916; Blacklock *et al.*, 1937). Others have postulated a virus infection and offer as evidence the observation that epidemics of gastro-enteritis and of colds seem often to occur together (Gunn, 1944). From the study of some 400 cases Sevitt (1945) concludes that paracolon and proteus bacilli are responsible for many cases of infantile gastro-enteritis. The disease may not represent a single entity, but may be the resultant of a number of different agents.

An Explanation of the Mechanism of Enteritis

If the rapid and abundant loss of fluid which is the cardinal sign of gastro-enteritis originates from the intestinal vascular plexus it must imply quite an abnormal permeability of the capillaries. Although many factors may contribute to produce this exaggerated leakage, it is probable that histamine ranks high on the list.

Histamine is a disintegration product of the amino-acid histidine, and the conversion can be effected by a variety of organisms acting on proteins; appreciable quantities of histamine are found in the stools of mammals. Experimentally, if administered in suitable amounts it is able to induce vomiting and diarrhoea, often with strong colicky pains. The effect is transitory owing to a rapid destruction of histamine by various agents, among which is the ferment histaminase, and perhaps also by a compensatory discharge of adrenaline (Feldberg, 1941).

Analysis of Some Methods of Treatment

If one bears in mind how many different methods of treatment have been proposed for enteritis, most of which are successful in at least some cases, one can reason that it is by no means essential to kill any pathogenic organisms in order to cure the disease.

Castor oil will often clear a mild diarrhoea in a matter of hours, and it can do so only by the rapid excretion of the irritating agents; its antiseptic powers are of course negligible. If we are prepared to admit that histamine is the principal cause of the diarrhoea, then its quick removal lowers its concentration around the intestinal vascular plexus, thus diminishing the permeability of the blood vessels. The natural resistance of the body can then cope with the organisms remaining in the gut.

Heisler (1928) and Moro (1929, 1930) recommended apples for enteritis. This treatment was widely conceded to be effective in mild cases, and various modifications, such as the use of bananas and carrots, were proposed by Continental paediatricians (Feer, 1929; Fanconi, 1930; and Glanzmann, 1939). The mode of action is supposed to be due to the adsorption of toxic and irritating agents by pectin (Salomon, 1936). Ramos (1941) published a study on the carob (*Ceratonia siliqua*), a tree of the Leguminosae family which is abundant in most Mediterranean countries. The pod, whose epicarp is almost as hard as wood, contains a sweet pulp much prized as fodder for horses. Ramos claims that roasted and pulverized carob pulp is very effective in gastro-enteritis.

While apples are rich in pectin (5.7 g. per kg. of apple pulp), a kilogram of a 10% carob suspension contains only 1.8 g. of this carbohydrate: hence the active material in the carob pulp cannot be pectin. Martin du Pan (1945a), who states that carob pulp is very rich in lignin, ascribes its therapeutic action to this. Freudenberg (1939) has written an interesting paper on this hydrophilous colloid, while Martin du Pan (1945b) states that one litre of a 5% carob suspension is able to adsorb 0.74 g. of histamine, whereas a 5% suspension of "aplona" (an apple product) is able to adsorb little more than half this quantity. On adsorption the amino-acids are not susceptible to the action of bacterial enzymes, and thus the formation of histamine and other irritants is much diminished.

The First Antihistaminic

In 1930 Best and McHenry reported that watery extracts of various organs were able to inactivate histamine through the action of a body to which they gave the name of histaminase. Rose and Browne (1938) thought that, although histaminase was not the only agent capable of destroying histamine, they had found that the mucosa of the small intestine contained large quantities of histaminase; it was therefore possible that in the absence of sufficient quantities of this enzyme histamine would display its usual toxic effects. Histaminase is believed to act on histamine by first separating ammonia from the side chain and then finally cracking the ring nucleus containing the two atoms of nitrogen and the three atoms of carbon.

Some years before the last war histaminase was marketed by the I. G. Farbenindustrie under the name of "torantil." Great hopes were entertained on its curative action in gastro-enteritis and in allergic conditions, and encouraging reports by Rigler (1936), Horster (1936), and others were published, but subsequent papers by Miller and Piness (1940) and others have been much less optimistic, so that the drug has now been practically forgotten.

Limitations of Sulpha Drug Therapy

It cannot be denied that some cases of gastro-enteritis do get well spontaneously, especially when the diarrhoea is so profuse that the toxic products are so diluted that they are rendered harmless. The dilution is further assisted when the fluid intake, oral or parenteral, is increased. There are several reports on the good results obtained from the use of sulpha derivatives in gastro-enteritis (Anderson, 1941; Meyer, 1943), but it is common experience to find them useless in some of the severer cases (Hinden, 1948). This can be explained by admitting that if the permeability of the intestinal vascular plexus exceeds a certain critical value, then death through dehydration may occur even in the presence of an efficient sulpha drug capable of killing any causative organisms. It is obvious that no sulpha derivative can neutralize or otherwise dispose of previously formed histamine or related bodies. It is recognized that sulpha drugs are also ineffective in non-specific diarrhoeas due to virus or other unrecognized pathogens.

Antihistamines in Gastro-enteritis

Starting from the assumption that histamine was the immediate cause of the fatal dehydration found in gastro-enteritis and was responsible for many of the toxic manifestations, it was decided to treat a number of cases with an antihistamine ("benadryl" in this series) combined later with a sulpha derivative. Moderately severe and severe cases only were selected, and the criteria were: the presence of pyrexia of 101° F. (38.3° C.) or over in the rectum; more than eight stools a day; and the presence of toxaemia, as shown by the rapid pulse, dyspnoea, and prostration. Vomiting, although present in the majority of cases, was not a constant finding.

The results are given in three Charts. In Chart 1 are included 24 cases treated by a short period of starvation during which half-normal saline or Hartmann's sodium lactate solutions were used orally, or Hartmann–Ringer solution parenterally. After 18 to 24 hours a proprietary buttermilk was given in gradually increasing amounts. No other medicinal measures were used. Four babies died, which gives a lower mortality than is usual in hospital cases; all cases were treated in private homes.

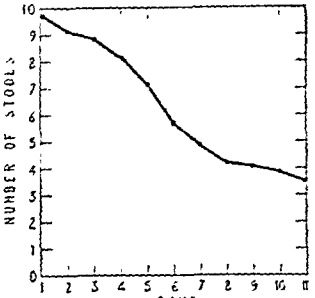

CHART 1.—Showing daily average number of stools in 24 cases treated by a short period of starvation during which various solutions were given.

In Chart 2, 16 cases are reviewed, and these received the same treatment as before but with the addition of

benadryl. Parenteral infusions were not required. Although rapid diminution in the number of stools was observed the fever was often uninfluenced and the condition of some patients deteriorated when the benadryl was stopped. When a sulpha derivative was concurrently administered rapid and permanent improvement set in.

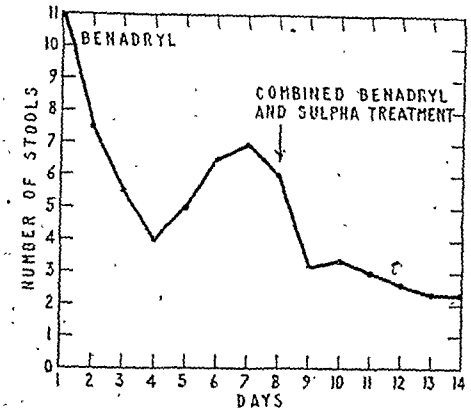

CHART 2.—Showing daily average number of stools in 16 cases treated as in Chart 1 but with benadryl and combined benadryl and sulpha drug added.

The choice of a sulpha derivative is no easy one, and so far can be considered to be largely empiric. Among the non-diffusible derivatives sulphaguanidine, sulphasuxidine, and phthalylsulphathiazole are available, while among the diffusible ones the best are probably sulphadiazine (Klose, 1947) and sulphamezathine. Blatt and his associates (1947) could discover no significant difference between the action of sulphathiazole and phthalylsulphathiazole. It is my impression, based on the observation of over 120 cases, that there is little to choose between sulphamezathine and phthalylsulphathiazole, and I always use one or the other of these two drugs.

As regards the dose of benadryl, I give 1 mg. for every month of age four-hourly, and when improvement sets in the same dose every six hours. This dosage is suitable for babies up to 5 months of age. From 6 months to 1 year the dose is 6 to 8 mg., administered in the same way.

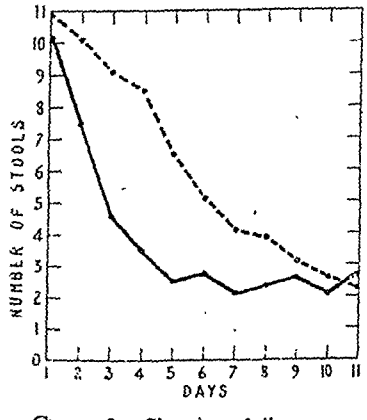

CHART 3.—Showing daily average number of stools in 42 cases treated with sulphamezathine alone (dotted line) and in 40 cases treated with sulphamezathine and benadryl (continuous line).

Chart 3 gives the results in 42 cases treated with sulphamezathine alone and in 40 cases treated with a combination of sulphamezathine and benadryl. It shows that the number of stools diminishes more rapidly when both drugs are used simultaneously, but it does not show the other favourable effects of using the combination of drugs, such as the very quick disappearance of the toxaemic symptoms. Vomiting, when present, ceases in a very short time; the prostration, dyspnoea, and tachycardia subside in most cases in a few hours. The continuous and irritating whine is replaced by a more peaceful cry; this is not surprising, as benadryl seems to have a sedative effect on the central nervous system, and in certain cases infants who have been unable to sleep owing to restlessness or colic repose quietly after a few doses. In no case was it necessary to resort to the parenteral administration of fluid; in fact, four cases among those treated showed a moderate but clearly visible generalized oedema. That this represents water retention is shown by a rapid increase of weight—as much as 200 g. or more in two or three days. The general condition of the patients is excellent, and the swelling subsides when the benadryl is stopped or the intervals between the doses are lengthened. There was only one death in the series treated with sulphamezathine and benadryl, but three deaths occurred in the series treated with sulphamezathine alone.

Conclusion

This communication is of the nature of a preliminary report, and further studies are necessary to assess the value of the combination of antihistamines and sulpha derivatives in the treatment of infantile gastro-enteritis. It is claimed that this combination does influence and materially shorten the course of the disease. Should this claim be confirmed some progress in the treatment of a distressing and often fatal condition will have been achieved.

Summary

The symptomatology of infantile gastro-enteritis can be explained, at least in part, as a manifestation of histamine intoxication.

The beneficial action of various therapeutic measures can be considered as being due to the removal or neutralization of histamine by rapid evacuation, by adsorption, or through antihistamines. Sulpha drugs, by acting on pathogenic organisms, may prevent the formation of histamine.

These measures often fail when the histamine intoxication is severe unless they destroy the histamine *in situ* or prevent the histamine from acting on the intestinal vascular plexus; only antihistamines can do this.

The Ministry of Health states that the latest figures for nursing and midwifery staffs in hospitals in England and Wales under the National Health Service continue to increase. In March of this year there were 5,600 more nurses than six months earlier, the total being 137,600. This figure includes 21,600 part-time workers—2,600 more than in September, 1948. The number of student nurses increased by 2,578 to 45,300 in the same period. The numbers of full-time midwives in hospitals rose from 4,381 to 4,813, pupil midwives from 3,184 to 3,677, and part-time midwives from 809 to 888. In the same six months full-time domestic staff increased from 99,733 to 100,514 and part-time from 23,131 to 25,065.

EXPERIENCE WITH A SYRINGE UNIT

BY

ANTHONY G. RICKARDS, M.D.

(*From the Department of Pathology, Royal Lancaster Infirmary*)

Many hospitals in this country are at present considering the establishment of a comprehensive syringe service. Such a unit has been in operation at this hospital for the past sixteen months, and it is felt that our experience may be of help to those about to undertake a similar service.

Method of Cleaning and Packing

Many different techniques have been tried in the sterilization and packing of syringes; the method of our choice is outlined below.

The syringes are first cleaned on the wards, and on arrival at the depot are placed in a bowl of soapy water or soapless detergent and boiled for 20 minutes. They are then rinsed in hot running water. These procedures are carried out with the piston pulled out of the barrel to about three-quarters of its distance. After rinsing well, clean warm water is drawn up and discarded with every syringe. The syringes are then dried in the hot-air oven again, with pistons pulled out to three-quarters of their distance, and, after cooling, a *little* liquid paraffin is applied to the bottom of the piston, the syringe being worked until an even coating of oil is obtained between piston and barrel.

The needles are similarly treated by boiling in soapy water, rinsing, and drying, and are then tested for sharpness and patency.

We have found that the simplest method of packing the syringes and needles is to place them in a hard glass test-tube of appropriate size containing a wad of cotton-wool on the bottom. The top of the tube is then similarly sealed with a cotton-wool plug. The method advocated by the Medical Research Council (War Memorandum, No. 15, 1945) differs from our own in that the assembled syringe is placed in a glass tube of such diameter that the barrel of the syringe is a loose fit but the flange rests on the top of the tube. The disadvantage of this latter procedure is that the top of each syringe must be covered with paper or "cellophane," tied or twisted, to keep its position. Moreover, paper subjected to the required heat often becomes very friable and cracks on handling.

The disadvantage of our method of packing is that the nozzle of the syringe is in direct contact with the plug of cotton-wool at the bottom of the tube. Sometimes pieces of wool become adherent to the nozzle and interfere with a good join between needle and syringe. This difficulty has been overcome by protecting the nozzle of the syringe with a Durham tube.

Two needles of different bore are threaded through a small slip of paper and placed in the same tube alongside the syringe in such a way that the paper prevents the points of the needles from touching the wool at the bottom of the tube.

Sterilization

Sterilization is carried out by placing the assembled units in wire baskets in a hot-air oven at a temperature of 160° C. for not less than one hour. A point of difficulty which often arises is the degree of temperature variation at different places within the same oven. The usual method of estimating the temperature is to place a thermometer through a slot in the top of the oven so that the mercury bulb is just within the cavity. It will sometimes be found that the temperature recorded this way is much lower than that at the bottom and sides of the oven, the variation being as much as 20° C. To overcome this difficulty it is best to place a thermometer in a test-tube plugged with wool and take recordings wherever it is intended to sterilize the syringes.

A further point to bear in mind is the rapid lowering of the oven temperature when cold syringes are placed within it. A considerable time may elapse before the oven regains its heat, and allowances for this factor must be made in the sterilizing time. As an alternative to dry sterilization an autoclave with drying facilities may be used. This would allow sterilization to be effected at a much lower temperature—a distinct advantage when dealing with glass-and-metal syringes.

Syringes

In the past all-glass syringes have been almost exclusively used where sterilization by hot air has been required, but several manufacturers are now producing glass syringes with metal nozzles which will withstand ordinary dry sterilizing heat at 160° C.

This syringe unit started with a stock of all-glass syringes, but these are now being replaced by the metal-and-glass types. There are two serious disadvantages to the all-glass syringe. The first is the fragility of the nozzle: approximately half of our breakages have been due to chipped glass nozzles. The second disadvantage lies in the poor join between needle and glass nozzle. This union is not as satisfactory as with the metal nozzle. A disadvantage encountered in the glass-and-metal syringe is that occasionally the solder melts at sterilizing temperature. This has not been a frequent occurrence in our experience, and when it does occur the syringe can usually be repaired by clamping it in a vertical position, applying gentle heat to the supported metal base, and allowing the solder to set again.

A recent innovation by a firm of syringe manufacturers is the production of interchangeable pistons and barrels. These, however, are as yet produced only in the all-glass type of syringe, but the innovation has much to commend it. A further point to remember is the desirability of eccentric nozzles. In syringes of 5-ml. volume and upwards eccentric nozzles are preferable to the central type, especially when using a metal-and-glass syringe. It will be found that some makes have a rather large metal base, rendering intravenous work difficult without eccentric nozzles. Some manufacturers of metal-and-glass syringes do not charge more for those with eccentric nozzles, but in other cases there is a considerable increase in cost.

Syringe Markings.—This problem has given more anxiety than any other in the syringe service. Originally it was found that the markings on the all-glass syringes had become almost invisible after six to eight weeks of constant use. The notice of the manufacturers was drawn to this fault, and they have improved the staying-power of the markings; but syringes still differ in the durability of the markings, and before large orders are placed it would be wise to test samples for this failing. Syringes with engraved markings are preferable to those of transfer type.

Number of Syringes required for the Service.—From experience it is found that three times the estimated daily turnover is the minimum number of syringes necessary to meet all requirements with efficiency. The estimation of the daily needs is a more difficult problem, and will vary with different types of hospitals. In this hospital, which has 230 beds and caters for fairly large out-patient needs,

it is found that the average daily turnover is in the region of 400 to 500 syringes.

Expenditure.—The following items of expenditure are based on the first year's experience with the service: cost of initial outlay on syringes and needles, £600; cost of replacements, £750; cost of labour, £300.

Breakages and Lost Syringes.—As will be seen from the expenditure figures, the cost of replacements has been very high during the first year's trial period, the average number of breakages being approximately 1% per day. If this rate of loss were to continue the service would hardly justify the expense. Approximately 50% of these losses were due to chipped and broken nozzles, and the introduction of metal nosepieces has proved a great saving. Moreover, to avoid clerical work, an over-generous attitude was originally adopted to the issue of syringes, but it is felt that the system is not conducive to careful handling on the part of the users, so a system has been instituted by which each ward and each department are allotted an adequate number of syringes, and sterilized units are issued only in exchange for used syringes. It is already becoming apparent that the introduction of metal-and-glass types, together with the more rigid check on the return of the syringes, is resulting in a decrease in the number of breakages.

It has been found that one person working eight hours a day is capable of servicing 300 syringes daily. This includes cleaning, assembling, sterilizing, and sharpening of needles.

Conclusion

It is hoped that this short account will save others needless expense and trouble. In particular it is emphasized that before ordering large numbers of syringes the manufacturer's claims should be thoroughly confirmed.

AMOEBIASIS IN ENGLAND AS A HOUSEHOLD DISEASE

BY

A. R. D. ADAMS, M.D., F.R.C.P.

AND

D. R. SEATON, M.B., M.R.C.P.

(From the Liverpool School of Tropical Medicine)

The recorded cases of acute amoebic dysentery or amoebic liver abscess occurring in persons who have not been out of Great Britain have for the most part been described as isolated instances, without regard to the source of the infection or of their infectivity to contacts. There have recently come to our notice three families, living in Liverpool, in each of which more than one member of the household was suffering from amoebiasis.

Case Reports

In July, 1947, we were consulted by a ship's officer who had developed dysentery during the previous few weeks. Examination of his stools showed vegetative *Entamoeba histolytica*. While receiving treatment in hospital he mentioned that his wife, who had not been overseas, had recently developed diarrhoea, and he inquired whether he might not have infected her with his complaint. He was assured that this was most unlikely, but, as his wife's diarrhoea continued, her stools were examined, and it was found that she, too, had acute amoebic dysentery.

In July, 1948, a boy aged 16 came under our care suffering from dysentery of undetermined causation which he had had intermittently for the previous two years. His stools contained blood, mucus, and numerous vegetative *E. histolytica*. This boy had dwelt all his life in a Liverpool slum. In the household were his mother, stepfather (a dock-labourer), and six other children, none of whom had lived out of Liverpool. On inquiry it was found that the boy's mother had been troubled with diarrhoea during the previous two months. Examination of her stools showed that she had acute amoebic dysentery. The remainder of the family were in good health, but it was found that the stepfather and four of the six children were passing cysts of *E. histolytica*. This family was also largely infected with threadworms, *Giardia lamblia*, and *Entamoeba coli*.

In February, 1949, a boy aged 7 was admitted under our care suffering from an intractable colitis which he had had for three years. His stools contained blood, mucus, and very large numbers of vegetative *E. histolytica*. This boy had never lived out of Liverpool. Specimens of faeces were obtained from his family, which consisted of his mother, stepfather, and three sisters. Of these the stepfather was found to be passing *E. histolytica* cysts. He had no history of dysentery, but it is of interest that he was born in India and had lived there until he was 13, since when (he is now 45) he has been in England. The remainder of the family had not been abroad.

Comment

The experience of these families serves as a reminder that amoebiasis is a condition which may easily spread in a household where personal cleanliness is not of a high order. This fact, though plain enough, has perhaps suffered from a lack of attention in this country. By contrast, French medical publications contain a number of instances of autochthonous amoebic dysentery in which association with proved carriers was established. Dopter (1917) reviews these; see also Garin and Lépine (1924).

Finally, we would stress the undesirability of diagnosing ulcerative colitis before excluding amoebic dysentery as a possible cause of the syndrome by microscopical examination of the stools by someone familiar with the appearance of *E. histolytica*. Two of the cases recorded here had been ill for years and were sadly reduced in health from the want of this precaution.

The National Tuberculosis Association of the United States has made 22 grants for research during the present year. Four of these awards are new; the remainder are for the continuance of work already started. Dr. E. R. Long, director of medical research, has given details of current work aided by the association. Professor James Waring, University of Colorado will be investigating the modification of tubercle formation to allow better access of drugs to the bacillus. Constitutional factors responsible for resistance and susceptibility to tuberculous infection are being investigated by Dr. P. B. Sawin, of Maine, and Dr. M. B. Lurie, of Philadelphia. Dr. D. Seligson of Vancouver, Washington, will be making a study of the blood pictures of tuberculous patients. Work on the virulence of strains of the organism and their resistance to drugs is being done by Dr. Mary Bunting, of Yale. Grants have also been made for further research into the factors responsible for caseation, and it is hoped these studies will indicate how tissue destruction in tuberculosis can be reduced. The chemistry of tuberculin is currently under examination in the Universities of Pennsylvania and Wisconsin; an investigation of moulds to discover an additional therapeutic agent against tuberculosis is being made at the University of Colorado. Most of the remaining grants are for clinical work in tuberculosis.

Medical Memoranda

Salt and Water Depletion in Surgical Practice

At the time of publication of Dr. Marriott's excellent article on the physiology and pathology of water and salt balance (*Journal*, 1947, 1, 245, 285, 328) attempts were being made in this hospital to reorganize the methods of dealing with this problem. The opportunity was taken of putting all Dr. Marriott's recommendations into practice, including the quantitative ward test for urinary chlorides which he suggested. Enough time has now elapsed to evaluate the results; the tests have been an unqualified success. All patients who are, or have been, vomiting severely, or who are having gastric suction, are given intravenous normal saline so long as the vomiting or suction continues, or until the urinary chlorides reach the level of 0.5 g.%, at which time a change is made to half-normal saline, rendered isotonic with glucose. A third solution is in use for infants, consisting of quarter-normal saline rendered isotonic with glucose. We found that the quantitative ward test can easily be carried out by a sister or staff nurse. It may be of interest to note that faeculent, and even faecal, vomiting seems no longer to be "a sign of impending death" in many cases if intelligent intravenous therapy is carried out.

It was realized from this reorganization that the fluid charts in use at that time were not satisfactory, and consequently a new chart was evolved. As this may be of interest to others, a copy of the chart which was used over a period of twenty-four hours in a case of acute jejunal obstruction is included. Its use is best explained by these instructions, which are posted in the ward for the information of nurses:

USE OF INTAKE AND OUTPUT CHARTS

1. The chart is to be kept with the patient's notes and other charts.

2. All measurements should be recorded *on the chart* at the time of making them. It will be seen that there are spaces provided against the various methods of intake and output, and *hourly totals* (giving figures to the nearest 4 fl. oz.) should be recorded in them.

3. Each chart ends at noon, and so it is desirable that all measurements are recorded up to date then. In other words, where possible, bladders should be emptied, vomits measured, and gastric suction bottles emptied and measured, and the measurements recorded.

4. Intravenous, subcutaneous, and rectal drips should be recorded when each bottle is empty.

5. In dehydrated patients—those having normal saline—all specimens of urine should be tested quantitatively for chloride, and the result recorded. Otherwise a daily record only is required.

6. The graph, which is a summation of the nurse's records, should be made up by the sister or senior nurse only.

The sister or senior nurse constructs the two graphs (intake and output) by the addition of figures already entered by the nurses. The urine chloride graph needs no explanation.

A Case of Polyorchidism

Spermatoceles, cysts of the cord, and other scrotal swellings are apt to be mistaken for an extra testicle, but, actually, cases of polyorchidism proved by operation or necropsy are extremely rare, and Boggon (1933) in an interesting article described what he said was the twelfth case on record. The following case is therefore considered unusual enough to be worth publication.

CASE REPORT

The patient was a German physician aged 50 who came concerning a swelling in the right side of his scrotum and double herniae. In 1940 he noticed a swelling in his right groin which he knew to be a hernia. It was easily reducible, and he began to use a truss. Soon he observed that the right testicle was enlarged, and he attributed this to pressure of the truss. In 1947 he found a small hernia on the left side and began to wear a double truss. On Feb. 22, 1948, he found for the first time a new swelling in the right side of his scrotum and, fearing that this might be a malignant tumour of some kind, he sought advice. His past and family history did not have any bearing on the case.

Physical examination and routine laboratory tests did not *show any evidence* of other disease. He was seen to have bilateral direct inguinal herniae, small in size. The left testicle and cord appeared normal. The right testicle was four times as big as the left and was translucent. Just above the right testicle and apparently attached to the cord was a smooth oval swelling the size of a small hen's egg. It was not attached to the skin and was opaque on transillumination. There was no tenderness on pressure. The cord on both sides felt normal. Rectal examination showed a moderately enlarged prostate but no abnormality of the seminal vesicles.

The nature of the lump above the right testicle was not clear. It was thought to be a haematoma of the cord due to some *trauma*, a *lipoma* of the cord, or, possibly, a malignant tumour. A long list of all the possibilities was written down, but the list did not include what the lump turned out to be. Because of the possibility of malignancy, exploration was suggested. The patient readily agreed, and requested that the hydrocele and the herniae be dealt with at the same time.

Operation.—On Feb. 28, under spinal analgesia, an incision was made over the right inguinal canal, the cord drawn upon, and the testicle delivered. The hydrocele was dealt with by excision of the sac, and the lump above the testicle was then examined. It was smooth in outline and readily dissected from the cord, to which it was but lightly adherent. Soon it became apparent that it had a cord and a vas deferens of its own, and

this extra cord was separated up to the internal ring, ligated, and divided. Both herniae were then repaired.

The pathologist's report was as follows: "*Gross examination*:—Oval-shaped mass of tissue, size 4 by 2.5 cm., with lateral-adhering, round, long cord-like structure, thickness 1 cm., length 10 cm. No epididymis-like structure was seen. The oval mass is covered by dense white connective tissue of the appearance of the tunica albuginea. On section the tissue is yellow, lobulated, and consists of fat tissue. Only on the border near the cord the tissue is dense and whitish red. The cord tissue consists of connective tissue and blood vessels and a vas deferens. *Microscopical examination*:—Only sections from the testicle itself were examined. Sections from three different places gave the same histological structure. The tissue consists mainly of fat tissue with interspersed stroma and blood vessels. On the outer periphery is a layer of dense connective tissue and some muscle fibres. Between this outer layer and the fat is an unsharply outlined narrow space filled with an eosin-stained fibrillar material and numerous spermatogonia and spermatozoa. Parenchymatous tissue of the type of the testicular tubuli was not seen. *Diagnosis*:—Lipoma of a degenerated testicle."

The patient is a married man with one child aged 12. He reports that his sexual functions are normal in every way, and that certainly he has never been oversexed. He is positive that until a week before the operation he had never noticed any abnormal swelling, other than the hydrocele, in the scrotal region.

F. T. RANSON, F.R.C.S.Ed., F.A.C.S.

Gastro-colic Fistula after Vagotomy for Stomal Ulcer

Bilateral resection of the vagus nerves is now often carried out in cases of stomal ulcer complicating previous gastro-enterostomy or partial gastrectomy. The following case history is therefore not without interest.

CASE REPORT

A clerk aged 49 was admitted to the Royal Victoria Infirmary, Newcastle-upon-Tyne, in October, 1948, with a history of left-sided abdominal pain for five months. Fifteen months previously he had had a partial gastrectomy for chronic duodenal ulcer. He had been perfectly well for ten months after the operation.

On examination he looked thin and anxious. There was tenderness and guarding of the left hypochondrium overlying a small ill-defined abdominal mass. A tentative diagnosis of stomal ulcer was confirmed by barium meal. The samples of gastric juice following an insulin test meal were too scanty to allow of anything but qualitative analysis. All samples contained free HCl.

Operation.—On Nov. 5, 1948, exploration showed the previous operation to have been an antecolic partial gastrectomy with distal prepyloric section. The scarred remains of an ulcer in the first part of the duodenum still remained. The probable cause of the stomal ulcer was thus not far to seek. The thickening of a stomal ulcer was palpable at the site of anastomosis between stomach and jejunum, at the lesser-curve end of the anastomosis. The small remaining prepyloric portion of the stomach and the first part of the duodenum were mobilized and excised distal to the ulcer. The duodenal stump was closed. The left lobe of the liver was then mobilized and a transhiatal bilateral resection of the vagus nerves carried out. About 2 in. (5 cm.) of each nerve was resected.

The post-operative course was complicated by diarrhoea and pronounced abdominal distension. The patient gradually improved, however, and was discharged home 18 days after operation, symptom-free.

One week later, on Nov. 30, he was again admitted to hospital. He had been well for five days after discharge, but for the last two days he had vomited after meals, and diarrhoea had accompanied the vomiting. On re-examination he looked ill and anxious. His tongue was dry and furred. The abdomen was slightly distended and there was visible peristalsis. The scar of the previous operation was soundly healed, but tenderness was again present in the left hypochondrium. Specimens of stool and vomitus were identical. A barium enema confirmed a diagnosis of gastro-colic fistula.

Second Operation.—On Dec. 3 the abdomen was again opened. A large gastro-jejuno-colic fistula was found and completely excised. The fistula involved the stomach, the efferent loop of intestine, and the transverse colon, and was obviously an extension of the stomal ulceration seen at the previous operation. Continuity was restored in the transverse colon and the jejunum. The remaining portion of stomach was further resected proximal to the stomal ulcer and anastomosed to the jejunum distal to the loop that had been repaired.

The post-operative course following the second operation was satisfactory apart from some initial collapse of the right lower lobe of the lung. The patient was again discharged home symptom-free 18 days after operation. Six weeks later he started work, and further follow-up continues.

COMMENT

It was unfortunate that no insulin test meal was carried out after vagus-nerve resection to test its adequacy. Such was the intention, but events forestalled it. The abdominal distension and diarrhoea for 14 days following this operation were signs which suggest that the nerve pathways had been suitably interrupted.

Some of the most encouraging results of vagus-nerve resection have been obtained in cases of stomal ulcer after gastro-enterostomy or partial gastrectomy. Excision of the ulcer mass followed by gastrectomy is the alternative operation. Few surgeons will disagree regarding the proportionate difficulties of the two procedures.

In this case, however, within a month of bilateral section of the vagus nerves the process of stomal ulceration at the site of a previous partial gastrectomy had proceeded to further penetration, with the development of a gastro-colic fistula.

JAMES A. KEY, M.B., F.R.C.S.,
First Assistant, Professorial Surgical Clinic,
Royal Victoria Infirmary, Newcastle-upon-Tyne.

With the introduction of death grants on July 5, 1949, the whole national insurance scheme has been brought into operation. Death grant is a cash payment of not more than £20 to help to meet the expenses connected with a death, and will usually be paid to the person bearing the funeral costs. Detailed provisions relating to death grant are contained in the National Insurance (Death Grant) Regulations which were laid before Parliament on June 27 by the Minister of National Insurance. As death grant is an entirely new benefit of State insurance towards which no contributions were paid before the new national insurance scheme began last year, there will at first be many deaths on which no death grant can be paid. It is estimated that a grant will be paid on rather less than half the deaths occurring during the next year, but the proportion of deaths on which payment can be made will gradually increase until the whole population is covered. No grant can be paid for the following deaths: (1) any death occurring before July 5, 1949; (2) the death of a man who was aged 65 or over on July 4, 1948, or the death of a woman who was aged 60 or over at that date; (3) the death under the age of 10 of any child born before July 5, 1948. A leaflet (N.I.49) explaining the conditions for receipt of a grant and how to claim one is available in local National Insurance offices and will be supplied by registrars to persons notifying a death. A special death certificate will also be provided free of charge by registrars for use in connexion with death grant and widow's benefit claims.

Reviews

CONTINENTAL HAEMATOLOGY

Bone Marrow Biopsy. By S. J. Leitner, M.D. English translation revised and edited by C. J. C. Britton, M.D., Ch.B., D.P.H., and E. Neumark, M.B., B.S., M.R.C.S., L.R.C.P. (Pp. 433; 7 plates (6 in colour), and 194 text-figures. £2 2s.) London: J. and A. Churchill. 1949.

In its original form this book was a monumental collection of the Continental literature on the subject, supplemented by the author's own views, and it is essentially a work of reference. It provides access to all the Continental literature during a period when the English-speaking world was cut off from such information. The author obviously found himself in a comparable position, for neither English nor American work receives the prominence it deserves. Those responsible for the English translation have attempted to rectify this last feature, at the same time making cuts in some of the more ponderous and pragmatic pronouncements so dear to the German mentality. In so doing the editors have thought fit to omit from the voluminous bibliography (amounting to more than 2,500 references) titles of papers which receive only brief and uncritical comment in the text. The reader is therefore left in doubt whether a reference is really worth consulting. He is also faced with the difficulty of knowing which is the pertinent reference, for there is no indication, by letter, title, or number, which is meant of the several contributions a given author has made in one year. On the whole the translation is good, but many sentences still exhibit an unwieldy Continental construction which seems strange to English ears (e.g., p. 161: "Schiappoli (1939) . . . as well as marrow hyperplasia . . . observed evidence of much extramedullary haemopoiesis in the liver and spleen").

Leitner's original text suffered greatly from his uncritical attitude towards the work of the many he had considered worthy of notice. His own observations and deductions are on the whole admirable, but he is at times prone to make dangerous teleological statements. For example, in speaking of the macropolycytes of pernicious anaemia (p. 80) he states: "Hypersegmentation may represent a compensatory process in which the body attempts to balance the reduced production of leucocytes caused by maturation arrest by keeping alive the aged cells." Most haematologists will take exception to the statement (p. 171) that, "though in myeloid leukaemia normoblasts are found in the peripheral blood, hypoplasia of erythropoiesis is present in the marrow." It is a pity that Leitner uses the term "erythraemia" as synonymous with erythroblastosis and erythroblastaemia (pp. 166–170). Such juggling with terms will cause confusion in the English-speaking community and should have been adjusted in the English translation. Despite these criticisms, and many others which might have been made, all haematologists will be indebted to Leitner for his compilation of the Continental literature, and to Britton and Neumark for making this work readily accessible in English.

LIONEL WHITBY.

PHYSIOLOGY OF VISION

The Physiology of the Eye. By Hugh Davson, D.Sc. With foreword by Sir Stewart Duke-Elder, K.C.V.O., D.Sc., Ph.D., M.D., F.R.C.S. (Pp. 451; 301 illustrations. £1 12s.) London: J. and A. Churchill. 1949.

Several books have been published recently on vision: Granit's *Sensory Mechanisms of the Retina*, Pirenne's *Vision and the Eye*, Willmer's *Retinal Structure and Colour Vision*, and Wright's *Researches on Normal and Defective Colour Vision*. All these form suitable reading for an advanced worker who is engaged in research, but are not what the student requires. They each discuss one aspect of the physiology of the eye in great detail, whereas the ideal work for the student should be less specialized. This is such a book; it is clearly written, unbiased, easy to read, and interesting. Moreover, the printing and illustrations are excellent.

The first section considers the transparent tissues—the cornea, the aqueous humour, and the crystalline lens. The mechanism of vision is discussed in the second part, which describes the retina, adaptation, and visual acuity. Section 3 gives an account of the muscles of the eye and their innervation, and part 4 contains an excellent description of visual perception, including stereoscopic vision and the perception of movement. Section 5 is devoted to the optics of the eye and the refractive errors, with their diagnosis and correction. This book is one which can be strongly recommended.

H. HARTRIDGE.

OCCUPATIONAL MARKS

Occupational Marks and Other Physical Signs. By Francesco Ronchese, M.D. Foreword by J. G. Downing, M.D. (Pp. 181; 151 illustrations. $5.50.) New York: Grune and Stratton. 1948.

This book will interest practitioners of forensic medicine and dermatologists and should be in the library of the necropsy room. Written by a dermatologist, it describes and illustrates in detail the "stigmata or marks" of occupation found on the skin and in the subcutaneous tissues. It is a summary of existing knowledge and an original contribution to clinical medicine.

In the foreword Dr. J. G. Downing says that "good physicians must be good detectives," to which Dr. Rochese adds, "This essay is not intended to make every man his own Sherlock Holmes." Every person shows positive or negative marks, especially upon his hands. "To be able to detect, solely from the legs of an individual murdered and dismembered, that it was a female, her station in life, [her] probable occupation, and [to give] valuable clues leading to her identity," was one of the author's achievements, as is noted in the introduction.

The text consists of several short chapters dealing with the general and special marks of many occupations, of sex, age, race, and social status. Particular attention is paid to the signs found on the hands of players of musical instruments, to special groups of hand-workers, to nail defects, tattoo marks, and to hair changes. One chapter describes deceptive marks and discusses legal problems, though from the American viewpoint.

Only positive marks are of value for identification: their absence means nothing. Diagnosis by these alone is a hazardous procedure. Knowledge of these indications may give a clue to the diagnosis of obscure skin lesions and aid in assessing compensation. Occupations and their techniques are constantly changing, and differ from country to country and from place to place. Individual idiosyncrasies sometimes confuse the picture, and a short absence from work may abolish the evidence. A rough classification is made of occupational marks, and is supported and illustrated by 151 figures, direct photographs or admirable line-drawings.

Most of the indications named are seen in this country, and general practitioners and housemen can make an interesting and profitable hobby out of their study. Works doctors are familiar with them: some of them have been described in recent literature. An extensive bibliography—but a poor index—completes an admirable clinical study. When writers of detective fiction discover this book a wealth of "new clues" will be available for use—and misuse.

H. E. COLLIER.

LOCAL ANALGESIA

A Surgeon's Guide to Local Anaesthesia. By C. E. Corlette, M.D., Ch.M.(Syd.), F.R.A.C.S. (Pp. 368; 200 illustrations. £1 15s.) Bristol: John Wright and Sons. 1948.

As the name implies, this book by a surgeon is written for surgeons; its value for anaesthetists is limited. It is a guide, but not a complete manual, on local analgesia. Its ultimate aim is shockless surgery, to be achieved by local analgesia in conjunction with the use of adrenaline to act as a physiological tourniquet. The first nine chapters describing drugs, the preparation of the patient, and the preparation and measurement of materials are excellent, and will be of value to all who read them. The remainder of the book, particularly the section on anatomy and the technique of local analgesia, will appeal principally to the practising surgeon.

R. R. MACINTOSH.

ANALGESIA IN MIDWIFERY

Obstetric Analgesia and Anesthesia. By Franklin F. Snyder, M.D. (Pp. 401. £1 12s. 6d.) Philadelphia and London: W. B. Saunders Company. 1949.

This book contains a large amount of information, much of which is original and based upon experimental work performed by the author and his colleagues at the Harvard Medical School, the Johns Hopkins Hospital, and the Chicago and Boston Lying-in Hospitals. The physiology and pathology of labour are dealt with at great length—for example, the chapter on "Respiration before Birth" contains 34 pages, and that on "Intrauterine Pneumonia" 37 pages. Part 2, which starts at page 213, is devoted to the treatment of pain during labour, and the various methods of general and local analgesia are considered in detail. Recent developments such as fractional caudal block are discussed, but curiously enough no mention is made of trichlorethylene.

This book will be invaluable to advanced specialists and research workers, but the casual anaesthetist or obstetrician may be somewhat disappointed, as theoretical considerations are given precedence over the practical details of individual techniques.

C. LANGTON HEWER.

CATHOLIC PSYCHOLOGY

The Driving Forces of Human Nature and Their Adjustment. By Thomas Verner Moore, Ph.D., M.D. (Pp. 461; illustrated. $6.50 or 35s.) New York: Grune and Stratton. London: William Heinemann Medical Books.

Father Moore is well known as the chief authority on psychology from the Catholic standpoint in the United States. The present volume is a complete and erudite exposition of this approach to the subject. After a historical introduction the subject matter is treated from the intellectual, emotional, and volitional aspects, and the biological, physiological, factorial, and philosophic contributions are all duly considered. As might be expected, more stress is laid on the importance of intellectual drive and control than might be met with in a similar treatise by a non-Catholic psychologist. To the latter, therefore, the approach might seem too didactic and somewhat superficial. Such an attitude may, however, be salutary when dealing with the normal individual and is to be criticized only when the subject is abnormal and suffering from psychoneurosis or psychosis. Nevertheless, Father Moore pays attention to Freud's work and his doctrines of conflict, repression, and regression, but he considers that Freud's more extreme doctrines of universal sexuality in deeply unconscious motivation apply only occasionally and to a few cases.

Medical readers will perhaps find most interest in the section on psychosomatic diseases and the visceral neuroses; which are adequately examined without the addition of any fresh concepts. In the section on volition there is, of course, a considerable weight of argument from Catholic philosophers brought to bear in an attempt to prove that human beings are provided with complete freedom of will. Again, the non-Catholic psychologist will find it difficult to follow the author with full confidence, but nevertheless the argument culminating in a discussion on the adjustment of man to God is well worth careful perusal. This is a valuable addition to psychological literature and will certainly repay the medical psychologist if he reads the whole 460 pages.

R. G. GORDON.

The sixth edition of Dr. Israel Wechsler's *Textbook of Clinical Neurology* (pp. 829; £2 2s.; London: W. B. Saunders Company) is as succinct as its predecessors, although many new facts have been added to its crowded pages. An excellent and extensive index simplifies reference, and on the page the facts are clearly stated in succinct sentences. There must be many examiners who would welcome such a prose style in their papers. Among the modifications is an opportune addition to the chapter by Dr. David Wechsler on psychological diagnosis which could with advantage be enlarged still further in later editions. Both psychometric examination and personality testing are now so important as parts of neurological case taking that detailed instruction about them is valuable and has a place in a book of this status. The work can once more be recommended to students of neurology.

AETIOLOGY OF INFANTILE ENTERITIS

Diarrhoea and vomiting in infancy is a syndrome rather than a specific clinical entity. Textbooks on paediatrics classify the condition under such broad headings as dietetic, parenteral, and infective, though in the last group accepted intestinal pathogens are rarely isolated from infants (with enteritis) under 1 year of age. However, in any diarrhoeal condition search should always be made for salmonella and dysentery organisms, nowadays easily and quickly identified, and for giardia. Sonne dysentery is particularly dangerous in an institution because of its high infectivity; giardia infection, causing a less acute diarrhoea, may go smouldering on in a nursery for weeks before attention is drawn to it; and recent evidence suggests that salmonella infection may not be so rare in infancy. Thus an outbreak of gastro-enteritis affecting 68 children, of whom 56 were under 1 year of age, occurred in a hospital population in Melbourne[1] and was apparently attributable, in part at least, to dust-borne contamination of food and food utensils.[2] In most institutional outbreaks, however, the most painstaking investigations have usually failed to demonstrate any specifically recognizable bacterial pathogen, so that the possibility has been considered that a virus may be the cause, particularly in the epidemic diarrhoea of the newborn, which workers in the U.S.A. have been inclined to regard as a disease *sui generis*.

In Britain attempts, both published and unpublished, to demonstrate virus in faeces or other material from newborn and older infants have been unsuccessful. Drs. Joan Taylor, B. W. Powell, and Joyce Wright, in a paper published elsewhere in this issue, refer to investigations by Dr. F. O. MacCallum. In extensive animal tests with tissues removed from four fatal cases of infantile gastro-enteritis he was unable to find any evidence in favour of a virus aetiology. It should, however, be emphasized that there are at least two forms of neonatal diarrhoea; the type that affects both mother and infant may well be due to a virus, as American investigations have suggested.

The view that certain Gram-negative bacteria, including the paracolon group, the proteus family, of which Morgan's bacillus is a member, and *Ps. pyocyanea*, may be causally related to infantile enteritis has long been held by different workers, but the fact that these bacteria are common concomitants in diarrhoeas due to other known causes and the difficulties of their specific identification have prevented general acceptance of their aetiological significance. Lately, close study of the serology of the lactose-fermenting coliform group by Kauffmann[3] and his colleagues has indicated that a few of the many serological types may be potentially more pathogenic than others, for 2 or 3 types were preponderantly present in cases of urinary infection, cholecystitis, and appendicitis. The first indication that a specific strain of *Bact. coli* may be associated with infantile enteritis came from Bray,[4] who isolated a serologically specific late maltose-fermenting organism with a characteristic seminal smell from 42 out of 44 infants admitted to hospital with "summer diarrhoea": he failed to find a similar organism in 100 contact infants without diarrhoea. Then, in the Aberdeen outbreak of gastro-enteritis in the spring of 1947, Giles and Sangster[5] identified a single serological type of *Bact. coli* in the faeces of 86 out of 92 infants suffering from the epidemic infection and from only five out of 116 infants with "parenteral" diarrhoea or mild infections not requiring hospital treatment. This organism was rarely isolated from healthy children or adults, but it was found in the faeces of four infants who twenty-four hours later developed diarrhoea.

Meanwhile a team of bacteriologists and paediatricians (the authors of the report in this issue), working with the support of the M.R.C. at the Hospital for Sick Children, Great Ormond Street, and the Central Public Health Laboratory, Colindale, had set themselves the task of investigating clinical, epidemiological, and bacteriological aspects of institutional outbreaks of infantile enteritis in maternity units and residential nurseries. The first of these outbreaks affected 20 babies (with 14 deaths) in the maternity unit of a Derbyshire hospital; 15 of the babies were bottle-fed, four partially breast-fed, and only one fully breast-fed. The outstanding symptom was diarrhoea with severe dehydration, preceded in some cases by lethargy, reluctance to feed, and loss of weight. The age at onset varied from 6 to 20 days. Rectal and nasopharyngeal swabs were obtained from nine acute cases, and from each of them a serologically specific *Bact. coli*, labelled D 433, was isolated. The same coliform organism was isolated from 10 babies (all artificially fed) who developed acute diarrhoea and vomiting in a mothers and babies' hostel in Middlesex, and again from eight affected babies in the same hostel eight months later. *Bact. coli* D 433 was also found

in the faeces of four babies living in a residential nursery in Hertfordshire where there was an outbreak of enteritis, and in 21 out of 23 infants who developed intercurrent diarrhoea, usually in small groups, in a children's hospital, but in none of 14 babies with mild intercurrent diarrhoea in a residential nursery and irregularly (6 out of 14 cases, 5 out of 24 cases) among children admitted to two hospitals with a diagnosis of gastro-enteritis. Further evidence suggesting an aetiological relationship of this organism to infantile diarrhoea was its disappearance from affected cases during convalescence, its appearance after relapses in infants not previously yielding positive cultures, and its absence from a large series of control healthy and sick babies. It was rarely found in the faeces of healthy adult contacts, but was found in nine out of 34 contact babies, none of whom later developed any clinical infection. It is noteworthy that the strains of *Bact. coli* isolated by Bray, by Giles and Sangster, and by Taylor and her colleagues were all serologically identical.

When a particular member of a family of organisms that normally live as saprophytes in the body is singled out as a possible pathogen the evidence must be specially convincing before its pathogenicity is accepted. A parallel to the present problem of the relationship of one or more serological types of *Bact. coli* to infantile enteritis may be drawn from the pneumococcus family. Pneumococci are present in the throats of 30-60% of healthy individuals, and scepticism about their pathogenicity would have been justified if it was not known that there are many different serological types, only a few of which—e.g., types 1, 2, 5, and 7—have epidemic propensities and are specifically associated with the communicable disease lobar pneumonia. These types are rarely found in the normal throat: on the other hand, certain types—6, 19, 23—are common in the throats of healthy children, and these same types are frequently associated with bronchopneumonia, which affects mostly young children with poor resistance to infection. Bronchopneumonia may therefore be regarded as an endogenous non-communicable infection and lobar pneumonia as an exogenous infectious disease. It may be permissible to postulate a similar division for infantile enteritis—the sporadic cases resulting from parenteral infection or other predisposing cause being associated with the endogenous coliform types, while outbreaks would be caused by the less frequent "epidemic" strains. Attempts to put such a hypothesis to the test would have to take into consideration the intricate serology of the coliform group, the difficulties of isolation and recognition of specific types, and the search for a suitable animal on which to test pathogenicity; the absence of an acute inflammatory reaction in the gut or the development of specific antibody in the affected infant; and the mode of spread of the infection and its selective attack on artificially fed babies under 1 year of age. But the quickening of interest in both the aetiology and treatment of this serious infection, illustrated by the two papers in this issue, augur well for its better control in the future.

EXCHANGE TRANSFUSION

The idea of exchange transfusion is an old one. Nearly three hundred years ago a list was published in the Philosophical Transactions of the Royal Society of London[1] of some of the possibilities of transfusion which trials could settle. No. 8 was as follows: "Whether a dog that is sick of some disease chiefly imputable to the mass of blood, may be cured by exchanging it for that of a sound dog." In the experiments of those times various animals were used, and since the donor could be sacrificed the exchange could be massive. The quantities necessary to secure various degrees of exchange in man have been estimated by Wiener and Wexler.[2] If blood is continuously withdrawn from a patient's circulation while the blood of a donor is infused into a different vein at an equal rate, the infusion and withdrawal of an amount of blood equal to twice the patient's blood volume will achieve about an 86% exchange; thus after transfusion and withdrawal of some 10 pints (5.7 litres) of blood from an adult only 14% of the patient's own blood will be left in his circulation.

It is evident that large-scale exchange transfusions can be performed on adult humans only when many blood donors are available. This is doubtless the reason why it is only recently, with the organization of large blood-transfusion centres, that the operation has been practised in any systematic way.[3] However, it is an easier procedure in an infant. The blood volume of a newborn infant is only about one-twentieth that of an adult: an adult can therefore harmlessly donate an amount of blood twice as great as the entire blood volume of an infant. Many methods of carrying out exchange transfusion in infants have been suggested, but that of Diamond[4] seems to be the simplest and best. Within a few hours of birth a fine plastic catheter is passed up the umbilical vein, and blood is withdrawn and replaced by that of the donor in small successive steps. The route that may be taken by the catheter is well illustrated in the article by Dr. J. J. van Loghem and his colleague which appeared in last week's issue.

4 *Proc. R. Soc. Med.*, 1947, 40, 546.
5 Wallerstein, H., *Amer. J. Dis. Child.*, 1947, 73, 19.
6 Mollison, P. L., and Cutbush, Marie, *Lancet*, 1948, 2, 522.

Exchange transfusion in infants has been practised almost exclusively for haemolytic disease of the newborn. In this condition, at birth and for a variable time afterwards, the infant's own (Rh-positive) erythrocytes are being haemolysed rapidly. Rh-negative erythrocytes are not susceptible to the haemolytic process, and the anaemia may be successfully combated by simple transfusion of Rh-negative blood. If massive transfusions of Rh-negative blood are given the infant's own erythropoiesis dies down, and for a few weeks practically no Rh-positive erythrocytes are to be found in the circulation, the infant relying almost entirely on the transfused erythrocytes. When this method of treatment is carried out it is a few days before the Rh-positive erythrocytes disappear from the circulation, and with exchange transfusion an attempt is made to remove almost all the Rh-positive erythrocytes during the period of the transfusion and thus leave the infant with only a few of its own erythrocytes. At least three possible advantages have been claimed for this operation: first, that it diminishes the likelihood of the development of kernicterus,[5] a toxic state which reaches its climax two to five days after birth and usually causes the death of the infant; secondly, that it diminishes the risk of overloading the circulation of severely anaemic infants; and, thirdly, that it simplifies treatment by enabling a sufficient number of Rh-negative erythrocytes to be introduced into the infant's circulation at a single operation so that no subsequent transfusions are needed.[6] This last claim seems to be the most soundly established, though the expeditious performance of the operation is likely to be achieved only in highly specialized centres.

Dr. van Loghem and his colleagues report a fatality rate of 22.5% in 160 infants treated by exchange transfusion. They contrast this figure with a fatality rate of 63.5% in a group of 88 infants not treated by exchange transfusion. These infants were elder siblings of some of those included in the "exchange" group; no details of their treatment are given, and the authors state, "It is impossible for us to compare the mortality rate of icterus gravis treated by simple blood transfusion with that of cases treated by exchange transfusion." At first sight it would seem that the findings of such a difference in fatality rates made any further trials unnecessary, but this conclusion may not be so well founded as it appears. First, some years ago icterus gravis was diagnosed only in cases which would now be considered as moderate or severe, whereas to-day cases are sometimes included in a series when the diagnosis is based entirely upon laboratory findings, such as a positive direct Coombs's test. Evidently, then, if the mortality of the disease a few years ago were to be compared with that of an untreated series collected to-day an apparent fall would almost certainly be noted. The second difficulty in making a comparison between a series treated "then" and "now" is that inherent in all comparisons of this kind: factors unconnected with exchange transfusion may help to lower mortality—for example, the availability of penicillin. Finally, though exchange transfusion is certainly better than no transfusion, the real point of interest is whether it is better than simple transfusion, and on this point there is still no good evidence.

The question whether the prognosis for a severe case of haemolytic disease of the newborn is improved by giving an exchange transfusion rather than a simple transfusion is an important one to solve. The successful performance of exchange transfusions demands special zeal on the part of the operator. The transfusion must be carried out within a certain time of birth and the operator must be prepared to undertake it at any time of the day or night. He cannot be expected to do this if it is likely that the infant has just as good a chance of recovery if treated by a simple drip transfusion of Rh-negative blood. It is to be doubted whether the relative merits of the two procedures can be settled by anything short of a properly controlled statistical trial in which the same investigators try out both methods of treatment in parallel. Nevertheless, such careful records as those of van Loghem and his colleagues provide invaluable data for those intending to practise exchange transfusion.

HIGH-VOLTAGE X RAYS

Installation has been completed at the Royal Cancer Hospital of the first of the two 30-million volt synchrotrons which, as made known in July, 1947,[1] have been under construction for the Medical Research Council. The second has been allocated to the department of radiotherapeutics in the University of Cambridge. Their function is to provide *x* rays of comparable voltage, at first for physical and biological research and later for therapeutic use in the irradiation of deep-seated cancers. Their advantage, compared with conventional *x*-ray sources, is that depth dosage is considerably increased compared with skin dosage.[2] It should therefore be possible to administer greater dosages to deep tumours without corresponding increase in the risk of surface injury. Much experimental work, extending probably over about a year, will be needed before the apparatus is used for treatment.

The synchrotron is in a basement laboratory which forms part of the physics department of the hospital under Professor W. V. Mayneord. The opening ceremony was on July 5, and the demonstrations which were given illustrated also the general work of the department

[1] *British Medical Journal*, 1947, 2, 101.
[2] Ibid., 1947, 1, 571.
[3] Ibid., 1946, 2, 951.
[4] Ibid., 1943, 1, 554.

in the application of nuclear physics to medicine. Subjects included the use in animals of cobalt-60 (Co^{60}) —the most probable artificial substitute for radium[3]; autoradiography as a research method, with the distribution of radioactive materials in tissue sections shown by the blackening of photographic films with which the tissue sections have been brought into contact; and the handling and clinical use of radio-isotopes. Devices for the remote control of radio-isotopes were shown, some of which have been designed and constructed in the department, and also a number of instruments specially designed for clinical work, and the clinical techniques used with radioactive sodium and iodine.

In the synchrotron, as in other *x*-ray sources, the generation of *x* rays is due to impact on a solid target of a beam of electrons which has previously been accelerated to a high energy.[2] The differences are in the level of energy to which the electrons are accelerated and the means used to accelerate them. Instead of being a "tube" in the ordinary sense of that word the synchrotron has the external form of a cylinder approximately four feet (122 cm.) in diameter. This is because the electron beam is accelerated round a circular track which is many times repeated. The earlier stages of acceleration are magnetic. The later stages are electrical—the accelerating force being arranged to vary in synchronism with the rotating electrons. Hence the name of the instrument. A further point of difference is that whereas a normal *x*-ray source is continuous the synchrotron operates on a pulse principle. It provides 50 pulses of high-energy electrons per second, and the same number of *x*-ray pulses—the duration of each pulse being some millionths of a second. In consequence, though the energy of the *x*-ray beam is very high, the average dosage rate is not high (probably about 10 roentgens per minute at one metre). The electron energies are expected to reach 30 million volts—which is the design figure—but the mean energy of the *x*-ray beam will necessarily be lower, because the electrons are not instantaneously brought to rest on hitting the target, but on the average penetrate it to an appreciable extent before their energy is converted into *x* rays. In other words, there is some loss of energy before *x*-ray generation takes place. This is the case with any form of *x*-ray source.

The first stage of investigation will be to define the physical limits of the *x*-ray beam. At the same time the efficacy of the initial protection which has been provided will have to be investigated, and any further steps which may be necessary must then be taken. This will involve a detailed series of measurements which may well extend over some months. Thirdly, it will be necessary to distinguish between stray electrons which have escaped from the synchrotron and the *x*-ray beam which it is its main function to supply. Only when this has been done can the beam itself be seriously studied. In this connexion Professor Mayneord and Dr. J. H. Martin of his department have been making measurements during the past two years on synchrotrons and betatrons —an earlier type of electron accelerator[2]—both in Great Britain and the United States. Their observations, soon to be published, afford the first comparison in internationally agreed units between the physical results obtained in the two countries.

In the second stage of investigation two related studies will be carried out. One will be of the depth dosage in a "water phantom" which adequately reproduces the course of absorption in the body. The other will be of the range of energies included in the *x*-ray beam. Finally, though the beam itself will be comparatively narrow, with the effective dosage falling off to half at a distance of some degrees off centre, it is likely that means for further canalizing the beam will also be considered. In the next stage the biological effects of the rays on a number of organisms, animals, and specific tissues will be observed. It is hoped in particular to study the effects on tissue cultures, in association with the Chester Beatty Research Institute of the Royal Cancer Hospital and other organizations, including the Strangeways Laboratory at Cambridge. Apart from the extension of the energy level at which such measurements have been made there is the further question of pulse irradiation—the repeated administration of a high dosage rate over very short periods.

A proposal for a gimbal-mounting,[4] which was discussed at an earlier stage, has been deferred until after the experimental period. The effect would be that the direction of the beam could be altered, as in *x*-ray installations generally. It is hoped in any case that the present site will be a temporary one.

The scientific development of the synchrotron has been largely due to a section of the Telecommunications Research Establishment, Great Malvern, which now forms part of the Atomic Energy Research Establishment at Harwell. The magnets and much of the electrical gear have been built by the English Electric Company, Stafford, in consultation with T.R.E., which is also responsible for the electronics. Development costs have been borne by the Medical Research Council. The hospital itself undertook the conversion of an old building to house the synchrotron and with the Medical Research Council has developed a fairly large centre for research in nuclear physics applied to medicine. There has been close co-operation for many years between the radiotherapeutic and the physics departments of the Royal Cancer Hospital. It is recognized to be essential in the present work that the closest touch be maintained between the clinic and the research laboratory.

ARBITRATION

On behalf of the Joint Committee and of the Central Consultants and Specialists Committee Sir Lionel Whitby in a letter to the Ministry of Health on July 5 asked for the establishment of a permanent negotiating machinery for consultants and specialists in the National Health Service. He also asked that the Minister or the representatives of the profession should have the right in the event of disagreement to refer for arbitration any matter within an agreed range of subjects, both parties to be bound by the award of the arbitrator. The agreed range of subjects should include any terms and conditions of service affecting remuneration. The Joint Committee also seek discussion on facilities for private treatment in hospital and for information about the payment of part-time clinical teachers. Until these matters are settled the Joint Committee advises consultants and specialists not to sign permanent contracts.

Of the three points in Sir Lionel's letter the one of outstanding importance is that on arbitration. We print in this week's *Supplement* the reply of the Ministry of Health to the Joint Committee. In this Sir William Douglas, secretary to the Ministry of Health, observes that the Ministry wants a permanent negotiating machinery, which, it is thought, should be established as a medical section of the Whitley mechanism. Sir William Douglas continues thus: "But you also want to add an absolute right to the medical profession, in the event of disagreement in discussion (within a prescribed range of subjects including remuneration), to refer the dispute to arbitration—both parties then to be bound by the arbitrator's decision. Here we certainly diverge from you, but more in the principle involved than what we conceive as likely actually to happen." Sir William draws attention to Clause 12 in the Amending Bill as providing the medical profession the same rights of arbitration already available to any other profession or trade. He points out that arbitration would be by mutual consent, although there are surviving wartime powers which go beyond this and which can be used by the medical profession so long as they are in force. The position, therefore, seems to be that the Ministry of Health agrees that there should be permanent negotiating machinery backed up by arbitration by mutual consent. It is not prepared to agree to *compulsory* resort to arbitration.

In the Committee Stage of the National Health Service (Amendment) Bill Mr. Aneurin Bevan made this important statement: "If both sides agree to go to arbitration, obviously the Minister would accept the consequences." The fixing of fees was not a matter upon which he could agree beforehand to go to arbitration. As those employed in the National Health Service were in contract with the Executive Councils or Regional Hospital Boards the employees were not Civil Servants and not in direct contract with the Crown. What was involved was a very substantial proportion of the budget. "We could not over this vast field . . . say beforehand that Parliament should put it out of its power to consider the fiscal consequences of an arbitration. If that were done I think it would be unconstitutional. That is why I am not agreeing beforehand to compulsory arbitration over the whole field. . . ." He reiterated later that if the Minister went to arbitration this involved acceptance of the results. A regulation would be laid before the House of Commons with the recommendation of the Government behind it. Only in the most exceptional circumstances would the House of Commons use its power to throw the regulation out, but it must have that residual right.

Conservative M.P.s in subsequent discussion agreed with Mr. Bevan that arbitration should not be made compulsory. Sir Hugh Lucas-Tooth, for example, observed that he did not quarrel with Mr. Bevan "in asserting that, subject to the general control of the House of Commons, he must retain control on these decisions." But he added that it would be unfair if the employer had the right under the Industrial Courts Act to insist on arbitration if the employed did not have an equal right. Mr. Bevan said later that under the Acts mentioned in Clause 12 there was no provision for compulsory arbitration. Referring to Sir Lionel Whitby's letter to *The Times* of June 20 and the quoted statement in it that "a code of conduct is unlikely to be arbitrable, but a simple proposal for a change in wages or salary almost certainly is," Mr. Bevan said, "I have not altered that statement. That still stands. I have not departed from that." He went on to say that under the two Acts referred to in Clause 12 mutual consent was necessary before arbitration took place: "I could not take the medical profession to arbitration if they did not want to go; they could not take me if I did not want to go; so we are on terms of complete equality here." Mr. Arthur Howard (Conservative M.P. for Westminster) pleaded that the Minister should make clear in a public statement that it was his intention to see that behind the conciliatory machinery there should be a second independent and impartial body to which either side should have the right of referring a matter in dispute. In Mr. Bevan's view the Conciliation Act of 1896 provided a number of agencies for reaching a settlement under mutually agreed arbitration, and he added that it was intended to establish a special Division of the

Industrial Court to deal with the National Health Service. Mr. Walter Elliot said that a misunderstanding had arisen and that it was a great pity that as late as June 20 this year "the negotiating body should still be in doubt as to what had been decided or proposed to them so long ago as October, 1947." He stressed that in the case of the medical profession the employer could legislate and was also negotiating with a body of employees who had declared that in no circumstances would they go on strike. When he was asked by Mr. Bevan whether on behalf of the Opposition he thought that there should be compulsory arbitration, Mr. Elliot replied, "No. Every hon. Gentleman who has spoken on this side has said no, because it is not possible." Mr. Elliot went on to say that they were trying to secure something in place of the power of compulsory arbitration, and he considered that the Minister's suggestion to create a special section of the Industrial Court concerned with the National Health Service was a step in advance.

The Joint Committee and the Central Consultants and Specialists Committee have asked for compulsory arbitration, and the reasons for it are well known. The medical profession, as Mr. Elliot observed, is in a different position from that of any other section of the community in that by the nature of its work it is unable to use the weapon of the strike. Nevertheless both the present Government and the Opposition, while agreeing on the need for arbitration machinery, refuse to allow it to be compulsory. This question is a matter which the Joint Committee will have to consider seriously when it meets representatives of the Ministry of Health. It is not clear what is meant by the last paragraph of Sir William Douglas's letter, and we should be reluctant to put on it what seems to be an obvious interpretation—namely, that unless matters are speedily settled the terms and conditions of service will not be made retrospective.

THE ONSET OF MENSTRUATION

Although the first menstrual period does not mark the beginning of the changes in physical development associated with the maturation of the genital system, it is an important landmark, since the age at which it occurs is easily ascertained. Elsewhere in this issue Drs. D. C. Wilson and I. Sutherland describe an investigation undertaken by the Institute of Social Medicine into the age of onset of menstruation in a cross-section sample of 1,338 girls in schools of Oxford city and county. As a survey it provides interesting indications about differences between menstruating and non-menstruating girls of the same age, particularly their height–weight ratios. Contrary to popular belief, these workers found that little difference existed between the age of the menarche of girls living in the town and in the country, and that the age incidence had not altered appreciably during the course of the last generation. The significance of the inquiry lies in the findings of the differences in the heights and weights between menstruating and non-menstruating girls in relation to their ages, and it thus confirms the work of Ellis.[1] To know that there is a mean difference of 3 in. (7.5 cm.) in height and of 25 lb. (11.34 kg.) in weight at the age of 11–12 and 1½ in. (3.75 cm.) and over 17 lb. (7.7 kg.) at the age of 15–16 is of some importance for purposes of research (particularly from records) on growth curves of large numbers of children. At the individual examination of girls, however, the clinical manifestations of puberty are so obvious that it would be unlikely for anyone to confuse the overweight child with the pre-pubescent one. If average curves for height and weight are used for comparative purposes it would seem that two curves should be substituted for the one commonly in use—one for those who have reached the menarche and one for those who have not. Even then these curves can be misleading, since the individual child's pattern of growth must be taken into account when comparison with the average curve is made.

Drs. Wilson and Sutherland found no evidence that the height and weight of girls aged 17 and 18 are in any way related to the age at which they first menstruated. The mean height and weight of girls (at the age of 17–18) who began to menstruate at 15 years and over were 65.1 in. (163 cm.) and 125.4 lb. (56.9 kg.); the figures for girls of the same age who began to menstruate at ages under 13 were 64.4 in. (161 cm.) and 125.4 lb. (56.9 kg.). This finding contrasts with that of Shuttleworth,[2] who found in a small group of girls that there was a rapid decrease in the rate of growth after the onset of menstruation. Girls whose menarche was later continued to grow after the height of those who had already begun to menstruate had become nearly stationary; in consequence those in the former group eventually overhauled the girls whose menarche was earlier and who were on the average taller during the period from 8½ to 12 years of age.

The sample studied by Drs. Wilson and Sutherland is not very large, and the figures obtained in a comparatively small city, favourably placed, together with a restricted rural area, may not necessarily correspond with those which would be obtained in densely populated or industrial areas. Further confirmatory evidence is necessary before the findings can be accepted for the country as a whole. The investigation, however, does provide information which medical practitioners, especially school medical officers, should bear in mind. The omission of any mention of the age of onset of the menarche in the school medical record card issued by the Ministry of Education must have been an oversight which no doubt will be remedied in due course. Though this information is unlikely to have much value at the ages of the three statutory examinations, it is of retrospective value and should be included.

BRITISH CONGRESS OF OBSTETRICS AND GYNAECOLOGY

TWELFTH MEETING IN LONDON

The twelfth British Congress of Obstetrics and Gynaecology was held at Friends House, London, on July 6, 7, and 8, under the presidency of Sir EARDLEY HOLLAND. Normally the Congress takes place every second or third year, but this was the first since that held in Edinburgh in 1939. Seven hundred members registered, four times as many as on the previous occasion.

The Congress was declared open by the MINISTER OF HEALTH. There was one feature of the National Health Service, he said, which gave rise to anxiety in the minds of obstetricians—namely, the division of responsibility between regional hospital boards and local health authorities, which, it was feared, might work to the disadvantage of the maternity service as a whole. In practice, he believed, this dichotomy would be bridged. A very fine team of people were now responsible for maternity services. Mr. Bevan also gave the provisional vital statistics for 1948—a maternal mortality rate of 1.01, compared with 3.13 in 1939; stillbirths 23.1, compared with 38.0; neonatal deaths 19.7, compared with 28.3; and infant mortality 34, compared with 50.6.

Modern Caesarean Section

Mr. C. MCINTOSH MARSHALL (Liverpool) introduced this subject by bringing forward statistics from 19 large hospitals in various parts of the country covering the period 1943 to 1947. The total number of deliveries at these hospitals was 125,179, and caesarean section had been carried out in 7,762 cases (6.2%). There had been 77 maternal deaths (0.99%) among these cases of caesarean section. The lower-segment operation was performed in 5,851 cases, with 35 deaths, and the classical operation in 1,734 cases, with 38 deaths. From these figures the classical operation came out three times worse than the lower-segment operation. "In my paper I speak of the classical operation with restraint and sadness; in public I never speak of it at all." Mr. Marshall recalled that in 1921, at the annual meeting of the British Medical Association at Newcastle, Professor Munro Kerr and Mr. Eardley Holland brought forward a similar collection of cases, covering the years 1911–20, and he compared this earlier series with that of 1943–7. In Kerr and Holland's collection were 1,218 cases of "favourable omen" (patient not in labour) with 19 deaths (1.56%); in the series now presented there were 3,126 such cases, with six deaths (0.19%). In the group of contracted pelvis and other cases (all cases being in labour), the maternal mortality in the earlier series was 4.41% and in the later series 0.96%. In the cases of eclampsia the figures were 32.1% and 7.69% respectively, in toxaemia 21.9% and 1.61%, and so with other indications or groups in which caesarean section had been performed. They had all been more than half aware, said Mr. Marshall, that the scope and safety of caesarean section in this country had been steadily increasing over the last ten years or more. Now the evidence was seen, and the extent of the success could be measured. It would be a pity, however, if they allowed themselves to rest there. The problems to-day were different but just as great as those of thirty years ago. The ideal antibiotic would be discovered, and chemotherapy must still have many gifts in store. Anaesthetic practices would be even more streamlined, though he could not conceive that any method which produced unconsciousness would be without risk. In theory the answers to thrombosis and embolism had been found. And all the time a more thoughtful devotion to their art would lead, more surely than any other thing, to a lessening of maternal mortality in any one of its aspects—and, above all, in caesarean section.

This introduction led to a lively discussion and an almost astronomical multiplication of statistics. Dr. NINIAN FALKINER (Dublin) brought forward figures from the Rotunda extending over seven years: vaginal deliveries were 34,489 and abdominal deliveries 841—the number of deaths following the former being 56 and the latter 15. The same advantage of the lower-segment operation over the classical came out in these figures as in Mr. Marshall's. Mr. A. W. PURDIE (London) described an investigation covering Middlesex county hospitals over the period 1943–7. There had been 1,667 caesarean sections performed, with 23 maternal deaths (1.38%). The total deliveries numbered 51,562. In the cases of "favourable omen" the lower-segment operation was performed 410 times, with four maternal deaths, and the classical 116 times, with one death. Mr. Purdie hoped that the Congress would not be followed by a spate of unnecessary and ill-judged caesarean sections.

"Failed Forceps" Cases

Mr. FRANK STABLER (Newcastle) said that at the Princess Mary Maternity Hospital the policy had been consistently pursued of not refusing section to septic cases, however bad the state of the patient before operation. For many years they were isolated in this practice, but now with improvements in technique and the advance of chemotherapy there was a sway towards their opinion; but they had not been wrong even before the sulphonamides and penicillin. He gave an analysis of his "failed forceps" cases since 1925. In 23 years his department had performed caesarean section on 144 women who had previously undergone attempted forceps extraction. There were 23 deaths (15.9%). Since the employment of sulphonamides in 1936 there had been 61 lower-segment caesarean sections after failed forceps, with six deaths (10%). In the last 10 years, when blood transfusion had been freely available, there had been 33 cases, with one death. Penicillin had been available only for three years, so that it was impossible to show its effect, but it could be said that nowadays a mortality in the region of 5% might be expected. The incidence of "failed forceps" cases was dwindling every year. He did not advocate caesarean section for all "failed forceps" cases. It should be employed for cases of obstructed labour who would need it if there was no question of infection. In 307 cases of "failed forceps," 50 caesarean sections were done.

Dr. KEVIN FEENEY (Dublin) said that too many caesarean sections were being performed. Enthusiasm for this operation should be tempered by common sense. To use it as an easy way out of obstetric difficulty was unjustifiable. In any case it should be performed only by senior members of the staff. Professor DOUGAL BAIRD (Aberdeen) estimated that in 10 years' time there would be 150,000 women in Great Britain who had been the subject of caesarean section. What would be the effect on their future childbearing? On the long-term view they must look forward to the time when caesarean section would not be necessary at all. Contracted pelvis was disappearing among the generation now growing up. It should not be forgotten that childbirth was a natural process.

Professor MUNRO KERR paid tribute to earlier pioneers than Eardley Holland and himself, and said how proud he was to hear these latest figures.

Professor SUNDE (Oslo) said that during the past seven and a half years 600 caesarean sections had been performed at his University Hospital, with five deaths (0.8%). The credit for this low mortality should be given primarily to penicillin and sulphathiazole in cases of infection, heparin treatment of thrombosis and embolism, and the organization of blood banks. Cases of toxaemia were not subjected to caesarean section, and it was his opinion that eclampsia and accidental haemorrhage should as a rule be regarded as contraindications. In older primiparae—over 40—age alone was not considered sufficient indication. Only in complications such as weak pains, large foetus, or breech presentation was section considered. Dr. REX MATTERS (Adelaide) was surprised to learn of the high proportion of cases in which section was done. At the antipodes they did not expect so high a percentage. Dr. G. W. THEOBALD (Bradford) told the Congress of a dream: wishing to visit the gynaecology department, he found that it had been abolished, that menstruation had been completely controlled, that the period of gestation had been reduced to three months, and that all deliveries were by caesarean section, to facilitate which a zip-fastener had been invented! Another slightly satirical speech came from Dr. BETHEL SOLOMONS (Dublin), who suggested that the next Congress should include a first-rate discussion on normal labour.

Pregnanediol in the Urine

Professor G. F. MARRIAN (Edinburgh) opened a discussion on the methods of assay and clinical significance of pregnanediol in the urine. He said that it had been established that during the menstrual period this steroid was excreted in the urine only during the luteal phase; during pregnancy it was excreted in increasing amounts up to the time of delivery, and in women in whose ovaries there were no corpora lutea the injection of progesterone was followed by the appearance of pregnanediol in the urine. Quantitative investigations suggested, however, that the amounts of pregnanediol present in the urine during the luteal phase of the menstrual cycle and during pregnancy might not be quantitatively related to the total endogenous secretion of progesterone or to that fraction of the latter utilized in producing the physiological changes characteristic of the hormone. If that were so it would be difficult on theoretical grounds to justify the use of pregnanediol determinations for clinical purposes. But it would be premature to be dogmatic on the question, and the clinician should adopt a cautious attitude. There were grounds for hoping that pregnanediol determinations would ultimately prove to have a real, though limited, clinical value.

Dr. G. I. M. SWYER (University College Hospital), after examining the results of 860 pregnanediol assays, considered that in general such assays had little to offer the practising clinician. There were no solid grounds for believing that pregnanediol excretion reflected at all closely the progesterone levels of the blood, and undoubtedly the latter were of far greater physiological significance. A simple, direct means of assessing the blood progesterone would supply evidence of much more clinical value than could ever be expected from the pregnanediol excretion in the urine.

The subsequent discussion, in which several French and Swiss workers joined, took very much the same line. Dr. P. M. F. BISHOP (London) said that it had brought out three important points: (1) that pregnanediol assays were time-consuming procedures requiring expert supervision and technical assistance; (2) that they called for close co-operation and understanding between the ward or out-patient department and the laboratory; and (3) that they were of such limited clinical value that the first reaction must be one of disappointment. He considered also that the problems of what might be called medical gynaecology were becoming so numerous and complicated that there was a good deal to be said for referring them to a special department. There was already a tendency to separate the investigation and treatment of infertility from the work of the routine gynaecological out-patient clinic. Dr. A. C. CROOKE (Birmingham) also described this "laborious and somewhat insensitive method" as of very little clinical value in studying abnormalities of menstruation.

Essential Hypertension in Pregnancy

A well-sustained discussion on this subject was opened by Professor G. F. PICKERING (London), who said that there seemed strong grounds for the provisional opinion that essential hypertension was an inherited condition, probably on a simple Mendelian basis, but a more extended survey of the children of hypertensive parents was necessary before such a conclusion could be regarded as fully established. As for the mechanism of the condition, there was no doubt that the raised arteriolar pressure was the result of vascular narrowing, for the cardiac output and the blood viscosity had been measured accurately and found normal. This vascular narrowing was likely to be due to a chemical abnormality either of the blood or of the vessels themselves.

Professor F. J. BROWNE (London) discussed diagnosis, course, and treatment. He considered that with the exception of those cases in which renal function was diminished or in which there was albuminuric retinitis pregnancy might be allowed to continue. As danger to the foetus arose only when blood pressure was above 160 mm. Hg systolic, 100 diastolic, efforts should be made to keep it below that level, and for this purpose the best remedy at present was rest, which should be enjoined throughout pregnancy and its extent increased as pregnancy proceeded, especially after the twenty-fifth week. Sympathectomy was useful in carefully selected cases of hypertension, and was said to give better results if the diastolic pressure was high and the pulse pressure low. It was contraindicated if the kidneys were badly damaged or if there was coronary disease or marked arteriosclerosis. It should be considered if the outlook for a successful pregnancy was bad, and especially if previous pregnancies had been unsuccessful.

Among Professor Browne's conclusions were: (1) chronic hypertension contributed about 25% of all forms of toxaemia of late pregnancy; (2) if the blood pressure at the start of pregnancy was 150/100 or over, the outlook for a viable child was poor; (3) there was no evidence that the hypertension was permanently aggravated by the pregnancy unless the patient developed superimposed pre-eclamptic toxaemia or eclampsia; (4) as pre-eclamptic toxaemia developed in 60% of chronic hypertensive cases, and the risk of chronic hypertension following pre-eclamptic toxaemia was 50%, it followed that about one-third of all women with chronic hypertension who became pregnant had their hypertension permanently aggravated in some degree.

A Warning against "Mutilating Operations"

Mr. G. F. GIBBERD (London) hoped that obstetricians would be on guard against mutilating operations on the sympathetic nervous system. The field of routine midwifery must not be allowed to be invaded by "destructive surgery still in an experimental stage." On the clinical side they were concerned with three well-recognized conditions: essential hypertension, toxaemia of pregnancy, and chronic nephritis; but the more critical they were the more they would find the need for another group unclassifiable in the present state of knowledge. Increased knowledge in the future would come from the fuller study of the relatively few well-defined examples of the disease under discussion rather than from statistical surveys of large numbers of patients placed in arbitrary classes with no clinical significance.

Professor R. J. KELLAR (Edinburgh) summarized the position thus: in normal pregnancy there was an increase in the cardiac output and the blood volume, and an increased flow through the muscles of the forearm and through the skin of the hands at cool room temperatures. In essential hypertension complicating pregnancy the changes were of the same order, with the exception that the flow through the forearm muscles was somewhat increased. The paradox of an increased cardiac output, such as occurred so commonly both in normal and in hypertensive pregnancies, could be explained only by the presence of the highly vascular uterus and the choriodecidual space. Here, therefore, was an example of a positively beneficent effect of pregnancy on the hypertensive process, albeit, alas, a temporary one. Mr. G. J. SOPHIAN (London) said that they were still ignorant of what happened in the early stages of hypertension, but he personally felt that functional vascular spasm due to sympathetic overactivity was the primary factor, and that it resulted, if too severe and long-continued, in an anatomical change in which the muscular reactivity of the vessels was replaced by the relative irresponsiveness of fibro-elastic tissue.

Caesarean Section in Hypertension

Professor T. N. A. JEFFCOATE (Liverpool) brought back the discussion to the previous theme of caesarean section, this time with regard to its place in chronic hypertension and complicating albuminuria. He said frankly that much of the discussion on caesarean section at the Congress was not up to the standard to be expected in a gathering of that kind. Many platitudes had been stated without evidence to support them, and the impression which must have gone out was that the art and science of obstetrics consisted in birth by the natural passages at all costs—the "costs" being the death of the child and very often injury to the mother. It reminded him of what used to be said many years ago—that caesarean section was a confession of failure, the implication being that a dead child was a sign of success. Results which he was able to bring forward showed that by delivering babies by caesarean section—the cases chosen being the worst possible material (that is to say, those in which the disease was most intense)—figures

relating to the children could be produced practically as good as those of spontaneous delivery at term, and in the case of very small babies caesarean section offered the best of all prospects in chronic hypertension complicated by albuminuria.

Mr. DICKSON WRIGHT discussed hypertension from the operating surgeon's point of view, and after a number of others had taken part Professor F. J. BROWNE replied to Mr. Gibberd's remarks about "mutilating surgery."

Carcinoma of the Uterus

A long session of the Congress was devoted to modern concepts in the diagnosis, prognosis, and treatment of carcinoma of the uterus. Dr. J. ERNEST AYRE (Montreal) said the vaginal smear method, first put forward by Papanicolaou in 1928, was a simple means of detection, but the "surface biopsy" modification, by scraping an area of the cervix, was a more sensitive and accurate method of diagnosis in early cases of cancer. A negative "surface biopsy"-scraping might be relied upon to indicate freedom from malignancy. Dr. GILBERT I. STRACHAN (Cardiff) described precancerous changes in the cervix on the basis of an investigation which had comprised the clinical examination of about 500 cases, including the histological examination of many hundreds of sections. He devoted special attention to one lesion of the cervix, namely, leucoplakia, which seemed to be the connecting link between the traumatized and infected cervix on the one hand and carcinoma on the other. Precancerous lesions were not observed at the growing edge of an established carcinoma, the probable reason being that when carcinomatous growth started it extended rapidly, blotting out any intermediate changes. The growing edge of an early carcinoma showed a sharp, sloping line of differentiation between the normal and the affected tissue.

Dr. A. GLUCKSMANN, of the Strangeways Research Laboratory, read a paper on prognosis based on biopsies. He found agreement between the early histological prognosis and five-year clinical results in 97% of cases, and held that suitably selected biopsies were reliable samples of the tumour and of its reaction to treatment. By the method he described patients with tumours curable by radiation methods could be selected for continued radiotherapy, while others were chosen for radical surgery.

Pelvic Exenteration

The Congress then listened to an exposition by Dr. ALEXANDER BRUNSCHWIG, of the Memorial Hospital, New York City, of his method of partial or complete exenteration for advanced uncontrolled cancers, principally of the cervix but also of the uterus and vulva, which he had been practising during the last two years. One type of operation consisted of complete excision of vagina, uterus, bladder, and pelvic lymph nodes, with bilateral implantation of the ureters into the pelvic colon; the other, of complete pelvic exenteration—excision of the bladder, vagina, and pelvic colon, together with the entire perineum, and implantation of both ureters into the colon above an end-colostomy. The partial pelvic exenteration had been done in 26 cases, with a surgical mortality of 19%. One patient had lived for 15 months and died of intercurrent disease, and others were living and well after a year or more. The complete pelvic exenteration had been carried out in 52 cases, with a surgical mortality of 23%, and seven patients were living and well after a period of from one year to 20 months. He defined surgical mortality as death occurring within a month of operation, whatever its cause.

Dr. JOE VINCENT MEIGS, of the Vincent Memorial Hospital, Boston, said that his group had done 35 similar operations, with about the same success as that reported by Dr. Brunschwig. It was the operation of choice in patients in whom radiation treatment had failed or who had fistula or recurrent tumours in the bladder or rectum, especially if they were in fair physical condition, as they so often were. Pictures were shown of these patients apparently, except for the inconvenience of a colostomy, living a normal life.

Mr. VICTOR BONNEY (London) said that some means should be found of distinguishing quite certainly the radiosensitive from the radio-resistant tumours before any treatment was decided. Professor VAN B. BASTIAANSE (Amsterdam) regretted that there had been no reference to the radical vaginal hysterectomy of Schauta. For the surgeon who had had experience in vaginal operations the Schauta operation was not difficult. Its primary mortality was low—only one death in about 250 cases at Amsterdam from 1942 to 1949—and the five-year cure rate was 55.34%. Professor MITRA (India) also drew attention to the many advantages of vaginal hysterectomy as compared with the abdominal approach.

Plea for Radiotherapy

Professor J. HEYMAN (Stockholm) took a different view. In the last six years the absolute cure rate at the Radiumhemmet had been 42% (the relative cure rate for Stage I being 70%, for Stage II, 42%, and for Stage III, 25%). They were very satisfied with the results of radiotherapy, and they had treated about 8,000 cases. He did not believe that there were any radio-resistant cases—there were cases which could not be cured by radiotherapy because they belonged to the group which was particularly malignant, but such cases could not be cured whatever the method used. If they had more extensive surgery it would mean a number of less competent surgeons at work, and they would not be likely to restrict themselves to the carefully selected case. Dr. MALCOLM DONALDSON urged the setting up by the Royal College of a Clinical Cancer Research Committee with an instruction to stimulate and co-ordinate mass investigations into the treatment of gynaecological cancer and to evaluate the results.

Maternal Mortality

Sir WILLIAM GILLIATT, president of the Royal College of Obstetricians and Gynaecologists, was applauded when he protested against the habit Ministers had of using maternal mortality statistics for political purposes. The Minister of Health in opening that Congress had spoken of the team work in the maternity service under the new Health Act and had then gone on to quote the figures, which were excellent in every way. But it might be suggested to the Minister that the National Health Service, which was 367 days old, could scarcely be responsible for the maternal mortality figures in 1948—at all events in the first half of that year. Sir William Gilliatt brought forward an analysis of maternal mortality in 1947 as compared with 1927. In 1927 the number of maternal deaths was 2,707, and in 1947 it was 1,058, a reduction of 61%. In the two groups of infections, post-abortional and puerperal, added together, the reduction had been as much as 82.75%. This he attributed to several factors: improvement in the planning of maternity units and the nursing of puerperal patients, the diminishing virulence of the streptococcus, the advent of the sulphonamides, the discovery of penicillin, and the better feeding of pregnant women. The reduction in mortality in the toxaemic group in 20 years had been 55.5%. Could this be carried further? During the past few years opinion had changed, and now not a low protein diet but a high one was advised, not only for normal pregnant women but also for those suffering from toxaemia, and the good results justified this striking change. In spite of official statistics, haemorrhage was the most common cause of maternal death. It was responsible directly for a large proportion of deaths in some of the other official groups. It was of the utmost importance to prevent unnecessary bleeding and to replace as soon as possible at least the amount of blood lost. He indicated the many ways in which unnecessary bleeding might be prevented.

Professor HILDA LLOYD (Birmingham) urged that normal confinements, after adequate and first-class antenatal care, should be conducted by midwives, whose training, it must be remembered, had been raised to a very high standard, far higher than that of the average newly qualified doctor who had had no further obstetric house appointments. The most urgent problem at the present time was an investigation into the aetiology, causation, and treatment of toxaemia, using the word in its broad sense.

Dr. PERCY STOCKS (Registrar-General's Office) said that about three-fifths of the fall in maternal sepsis between 1928–30 and 1947 could be attributed to the new drugs, the other two-fifths being due to improvements in antiseptic technique, including

the wearing of masks, and routine examination, and to greater antenatal care.

Midwifery and the General Practitioner

Sir EARDLEY HOLLAND, president of the Congress, said that very few individual obstetricians could get a real insight into the causation of maternal mortality, because they saw relatively so few deaths. He himself did not gain such an insight until at the beginning of the war it became one of his duties to investigate every maternal death in the home counties. He found the commonest cause to be shock or haemorrhage or both. Another generalization was that a high proportion of deaths were avoidable. He believed that in the home counties over three years at least half the maternal deaths would have been avoided by quite ordinary standards of midwifery.

Speaking of domiciliary practice, Sir Eardley Holland described the term "general-practitioner obstetrician" as an "absolute sham" and a misuse of the word "obstetrician." In America they had maternal mortality committees, and he thought such committees might be appointed here, consisting of clinical obstetricians and one or two specialists, to report on maternal deaths and analyse them, as was done in the American bi-monthly *Obstetrical and Gynecological Survey*.

Mr. G. W. THEOBALD (Bradford) said that owing to the dichotomy in the service some medical officers of health were persuading women who wanted to be attended by midwives to employ doctors, because if midwives were sent out the charge fell locally, whereas if the general practitioner went it fell on State funds. He believed that recent administrative developments had put back the clock of obstetric advance, though no doubt the blood transfusion service, the use of sulphonamides and penicillin, and so on, would mask the setback.

Dr. KOSMAK (New York) gave further details about the maternal mortality committees in the United States. Practically every large city now had one of these official juries investigating individual deaths. A great many confinements had been found to take place in so-called maternity homes which were poorly equipped, and in which the doctor was privileged to do anything he wanted, from induction of labour to caesarean section, though he might not be qualified to perform it. Through the Department of Health a set of rules and regulations had been drawn up which were in force at the present time and had proved to be of great value. Under these no general practitioner who undertook the care of a maternity case in one of these institutions was allowed to perform any major surgery without consultation. Among others who joined in this discussion were Dame LOUISE MCILROY, Professor DUGALD BAIRD, and Dr. H. R. MACLENNAN.

Sir WILLIAM GILLIATT said that he thought Sir Eardley Holland's suggestion for a committee to be appointed to investigate all maternal deaths was a good one, and that it might be transmitted to the Maternity and Midwifery Standing Advisory Committee recently constituted by the Minister, of which he was chairman.

Further Discussions

A short discussion on the management of pregnancy in diabetics was opened by Dr. WILFRID OAKLEY and Mr. JOHN PEEL (King's College Hospital) in a joint paper. They showed that the foetal mortality rate in the pre-diabetic state reached its maximum in the two-year period immediately preceding the onset of diabetes. The duration and severity of the maternal diabetes appeared to be unrelated to the high foetal mortality, but the degree of control was an important factor. Without proper control of diabetes a significant number of mothers died in diabetic coma, but with proper control the maternal mortality was influenced only very slightly if at all by the presence of the disease. The incidence of hydramnios was high in pregnancy in diabetic women, and that of toxaemia was greater than in non-diabetic women, the highest incidence being in the last three weeks. Reference was made to the high rate of neonatal death in babies born of diabetic mothers. The majority of the deaths occurred within 48 hours.

Dr. PETERSEN (Copenhagen) reported a study of 205 pregnancies in 152 diabetics in two lying-in hospitals in Denmark. He related the foetal mortality to the age of onset of diabetes in the mother. Thus with mothers in whom the diabetes had begun at age 1 to 15 the foetal mortality was 42%; with mothers who first had the disease between the ages of 16 and 24 the foetal mortality was 29%; and in those in whom diabetes did not appear before the age of 25 the foetal mortality was only 6%.

Doubt was cast upon the many statistics given in the course of this discussion when Professor F. J. BROWNE said that an expert statistician, looking at these figures, could "drive a horse and cart through them."

Hernia of the pouch of Douglas was the subject of another brief discussion, opened by Mr. C. D. READ (Chelsea Hospital for Women), and continued by Mr. VICTOR BONNEY, Dr. GREEN-ARMYTAGE, and others.

Throughout the Congress and at every session many members who wished to contribute to the discussions had to be denied owing to lack of time. Visits were paid to a number of hospitals, and at University College Hospital delegates were able to watch by means of television the operations performed in the theatre. This was done by means of Marconi *portable* television equipment. Two cameras, mounted in the *gallery* of the theatre, with their telephoto lenses trained on the operating table, recorded every phase of the operations, which were projected on the 20-in. screens of two Monitor receivers installed in a separate lecture hall.

Social occasions in connexion with the Congress included a banquet at Guildhall and a number of receptions. The next Congress will be held at Leeds in 1952.

COMMONWEALTH AND EMPIRE TUBERCULOSIS CONFERENCE

The second Commonwealth and Empire Health and Tuberculosis Conference, organized by the National Association for the Prevention of Tuberculosis, which is celebrating its fiftieth anniversary, was held at the Central Hall, Westminster, from July 5 to 8. It was attended by 1,200 medical and lay delegates and observers, 160 of whom came from overseas. Although pre-eminently a Commonwealth Conference, the United States, every country in Western Europe, and many foreign countries in Asia and Africa were represented. The discussions were on tuberculosis as a world problem, trends in modern treatment, tuberculosis schemes of local authorities and schemes in the Colonies, the prevention and the detection of the disease, and the psychological and social readaptation of the chronic sufferer. The conference was addressed by several members of the Government, including the Secretary of State for the Colonies, the Secretary of State for Commonwealth Relations, and the Parliamentary Secretary to the Ministry of Food. The Minister of Health sent a message in which he spoke of advances in the control of tuberculosis under the National Health Service. He referred to facilities for mass radiography, the availability of B.C.G. vaccination "within prudent and controlled limits," and the establishment as a statutory duty of the care and aftercare of tuberculous patients by local health authorities. Sir Robert Arthur Young presided over the first sessions of the conference.

Streptomycin

A discussion on trends in the modern treatment of tuberculosis turned largely upon streptomycin, on which several experts from other countries addressed the conference. Professor ETIENNE BERNARD, professor in the Faculty of Medicine, University of Paris, said that streptomycin had transformed the prognosis of miliary tuberculosis of the lungs. But there were two qualifications to be made. During the treatment of tuberculosis with streptomycin, or even after treatment, there sometimes appeared a suppurative cervical adenitis. No treatment was of any value, and in some of these cases, in spite of clearance of the lung fields, the patients died of cachexia. Organisms from the glandular pus showed streptomycin resistance. In other cases of acute miliary tuberculosis, after a complet

cure had apparently been effected a relapse occurred within six months or a year, with reappearance of miliary lesions in both lung fields and extra-pulmonary lesions. The relapses were severe; renewal of treatment was disappointing owing to streptomycin resistance, and some of the patients died in spite of the addition of para-aminosalicylic acid to the streptomycin. Clearing of the lung shadows did not therefore mean that the contest was definitely won, and the late danger of a relapse of miliary tuberculosis, with an unfavourable prognosis, must be borne in mind.

Dr. CECIL GORDON SHAVER, superintendent of the Niagara Peninsula Sanatorium Association, gave an account of the use of streptomycin in Canada. The drug became available to Canadian sanatoria early in 1947, but the cost at first was too high for its general use. In July, 1948, however, free distribution of streptomycin was made possible through federal health grants, and from then until the end of March 1,786 patients in Ontario sanatoria had received 1,950 free courses of treatment. Symptomatic improvement had been noted in practically every case, the main exceptions being those with fibro-cavernous disease. One point generally noted was that cases with fever showed a gradual subsidence of temperature unlike the usual course of tuberculous disease. Of seven adult cases of tuberculous meningitis good results were obtained in four cases but three showed relapses of varying severity. Of 13 cases of miliary tuberculosis 10 showed a good initial response, but six of these subsequently developed meningitis and died. In pulmonary tuberculosis exudative lesions had responded extremely well; in spreading disease, of 116 cases 75 (64%) showed improvement beyond ordinary expectations. In this group there had been five cases of relapse, leaving a total of 60% improved. In 27 cases there was no improvement, and in the remaining 14 the condition became worse under treatment.

After discussing the results in various tuberculous conditions Dr. Shaver said that most of the sanatoria were using a dose of one gramme daily for periods of 42 to 120 days. Investigation of the resistance of tubercle bacilli to streptomycin showed that resistance did not often develop before the end of six weeks; so that if a six-weeks course of treatment would produce the desired result, the drug should be discontinued at or before the end of that period. The Toronto Hospital at Weston reported that in the majority of cases in which streptomycin resistance appeared in the isolated organisms such resistance occurred from five to seven weeks after the beginning of treatment. In a few cases complete streptomycin resistance was not apparent at the conclusion of therapy, but showed itself a few months later. It was not possible as yet to state whether or not resistant bacilli might regain sensitivity.

British Experience of Modern Treatment

Dr. GEOFFREY MARSHALL (Brompton Hospital), after reciting the history of various treatments, some of which had been overrated and afterwards discarded, said that in streptomycin in the treatment of tuberculous meningitis they had something very different from what had gone before. He went on to describe the investigation of the value of streptomycin in pulmonary tuberculosis—an investigation under much more critical control than had ever been planned before in the case of a therapeutic remedy. The improvement under streptomycin was undoubted, but it was not lasting; most of the patients started to relapse during the latter part of the first six months of the trial.

Streptomycin was a valuable but a short-lived remedy. With the development of streptomycin-resistant strains, the preparation was no longer of value to the patient. The danger was that such patients might infect a younger person, who might contract a tuberculous meningitis which was streptomycin-resistant. A particular value of streptomycin was in the case of a patient who should have collapse therapy but was too ill to undergo it. For a limited time such a patient improved greatly under the drug, but the collapse therapy must be instituted within three months. Streptomycin could be used as an "umbrella" for surgery, but it was better to keep it in reserve; it was more effective as a remedy than as a preventive. The value of para-aminosalicylic acid was being tested. The Medical Research Council was conducting a rigid trial of PAS alone, streptomycin alone, and a combination of the two.

Mr. C. PRICE THOMAS (Westminster Hospital) described recent advances in thoracic surgery, particularly resection of the lung. There were some who thought that all patients should be subjected to resection, but this had its dangers, especially non-healing of the bronchus, the patients tending to get empyemas of the lung, and the disease spreading during the actual operative process. He agreed with Dr. Geoffrey Marshall that streptomycin had little power to prevent complications, but it was able to deal with them when they arrived. Operation could be done without streptomycin, but it was desirable that it be used as a cover; he started the administration of streptomycin one day before operation.

Professor J. LEHMANN (Gothenburg) said that chemotherapeutic agents could be considered only as an aid in the treatment of tuberculosis, and that all physical measures should still be used. Treatment with the present therapeutic agents was "only a faltering step in a long and stony way."

Collapse Therapy in Domiciliary Treatment

The increased demand for hospital and sanatorium beds and for more highly trained doctors and nurses consequent upon the newer treatments was emphasized by Dr. J. G. SCADDING (Institute of Diseases of the Chest, London). Streptomycin had greatly increased the average period required for institutional care—care, moreover, in a well-equipped and fully staffed institution. This applied alike to tuberculous meningitis, to miliary tuberculosis, and to pulmonary tuberculosis. One of the great advantages of streptomycin was that it enabled patients previously considered unsuitable for surgical treatment to undergo that treatment, but this needed trained teams and again prolonged the time necessary for institutional care.

The increased demand for beds as a result of these new measures, Dr. Scadding continued, had led to the use of collapse therapy as part of domiciliary treatment in suitable cases. Here he gave an account of work done along these lines in Southwark and in Hammersmith. At one clinic, out of some 90 new patients, roughly two-thirds were treated in their own homes by collapse therapy, with the result that it had been possible to cancel a number of applications for sanatorium accommodation. The scheme required careful co-operation between doctor, nurse, and social worker, but it seemed as if collapse therapy was likely to play an increasing part in the domiciliary treatment of pulmonary tuberculosis. Those engaged in this work had no doubt about the success of these measures, and the improvement in the morale of the patient was very evident. Such measures, however, must continue to be regarded as palliative only, and there should be no undue complacency following on their apparent success.

Dr. E. RIST (France) urged the advantages of artificial pneumothorax. Streptomycin and PAS were valuable, but they had their dangers and their failures. Pneumothorax on its introduction was hailed as the greatest advance ever made, but afterwards it underwent an unjustified decline in favour. He was surprised to find some colleagues preferring thoracoplasty and to read in American literature that many physicians preferred long bed rest to the institution of an artificial pneumothorax. After long experience he could affirm that the results obtained after collapse were more permanent than after bed rest only.

Para-aminosalicylic Acid

Dr. G. BIRATH (Sweden) mentioned the clinical advantages of PAS. An investigation of 150 to 200 cases had been made by the Swedish National Tuberculosis Association, and the results showed a significant difference in every respect, even radiologically, in favour of the PAS-treated cases. The effect was not so rapid as that of streptomycin, although a striking improvement might occur during the first six weeks of treatment. One of the main indications in toxic cases was to employ thoracoplasty, maintaining the patient on PAS throughout; the fever disappeared and the patient gained weight. The development of resistant micro-organisms seemed very rare.

Dr. E. K. PRITCHARD (Southwark) said that Dr. Toussaint, who originated collapse therapy in domiciliary treatment in Southwark, had since left that neighbourhood and he himself had continued to treat tuberculous patients in their homes. During the first eighteen months over 100 cases had been treated, and 31% were now sputum-free; 10% of these patients had died, but in a number of them the disease was fairly advanced before they came into his hands. About half were treated with pneumoperitoneum and half with pneumothorax; the former, he thought, should be the initial measure in the patient's home, except in very light and early cases. Any hope of doing good work in domiciliary treatment depended to a very large extent upon the keenness and efficiency of the health visitor. It was her business to get the patients into the right frame of mind, and to look in on them at odd times and make sure they were resting. PAS had a place in domiciliary treatment, and he had used it in a number of cases.

The long discussion was summed up by Dr. G. S. TODD (King Edward VII Sanatorium, Midhurst), who paid a special tribute to matrons and nurses. Modern treatment would be useless unless there was a competent team. The doctor might see the patient for five minutes every day, but the nurses saw him for hours and had to carry out many onerous duties.

Tuberculosis a World Problem

Another session of the conference was devoted to the consideration of tuberculosis as a world problem. It was opened by Dr. J. E. PERKINS (National Tuberculosis Association, U.S.A.). Dr. Perkins said that in the United States the death rate from tuberculosis was only 30 per 100,000, but tuberculosis was still a leading cause of death in the critically important age groups 15–34. In India the mortality was five times as high as in the United States, and in China even higher; in Asia as a whole the death rate was estimated by the World Health Organization to be between 260 and 360 per 100,000. The first WHO Assembly recognized the magnitude of the problem by giving it top priority for action by the secretariat, but the amount set aside to finance the work was pitifully small.

After speaking of the continuing need for voluntary organizations he pleaded for a clear understanding between these and the World Health Organization. The International Union against Tuberculosis, which gave invaluable service in the past in stimulating the exchange of scientific information through periodical international conferences and in other ways, went into hibernation during the war, but the stage was now set for its return.

A number of delegates then gave information about the position in their respective countries. Dr. C. J. W. BECKWITH (Canadian Tuberculosis Association) said that during the last twenty years the death rate from all forms of tuberculosis in Canada had been reduced by about 50%. In 1926 it was 86·5 per 100,000, in 1947 it was 43.4. It was believed that with intelligent and balanced use of the various measures for control and treatment, including the increasing use of B.C.G. vaccination, this death rate and the morbidity figures could be reduced appreciably further. Sanatorium treatment was provided without charge by law in five provinces; five provinces had legislation for compulsory segregation, and all the provinces had schemes for the support of the family while the breadwinner received treatment.

Dr. FRANK RETIEF (Johannesburg) said that during 1947–8 over 25,000 new entrants to the mining industry from the native territories within the Union of South Africa were examined by miniature radiography, and the radiological findings debarred 199 of them from employment. The death rate from pulmonary tuberculosis in native labourers in the gold mines was 52 per 100,000; the European death rate in the Union was 32, one of the lowest in the world. Miss RUTH BRIDGES gave an account of a special investigation into the relatively high incidence of tuberculosis among nurses in New Zealand.

The Indian Subcontinent

Dr. RAM CHANDRA ADHIKARI (Bengal Tuberculosis Association) painted a sombre picture of tuberculosis in India, where, it was estimated, at least half a million people died of the disease every year and there were about 2½ million open cases in the country. The death rate from tuberculosis in Lucknow was 419 per 100,000, compared with 96 in London. His tale, he said, was unrelieved by any silver lining. But mass inoculation must be introduced at once, and it was a great relief to learn that the Government of India, in spite of so many preoccupations, had seriously taken up the task of manufacturing B.C.G. vaccine on a large scale.

Dr. RIAZ ALI SHAH (Pakistan) said that in his country there were fewer than 700 beds for tuberculosis and only seven clinics. A Pakistan National Tuberculosis Association had been started; doctors had been sent to India and to Scandinavia for training, and 100 tuberculosis beds had been added to the hospital at Karachi. Dr. G. RANAWAKE (Ceylon) said that in his country every public health officer was being trained to become a potential tuberculosis officer, particularly in relation to the families and contacts of sanatorium patients. Ceylon was endeavouring also to make the sanatorium part and parcel of the hospital, instead of allowing the tuberculous patient to be the "private property" of the tuberculosis specialist.

Dr. J. B. MCDOUGALL, secretary of the WHO Expert Committee on Tuberculosis, described how during the past two years the World Health Organization had accepted the responsibility for a world survey of tuberculosis. This summer a number of areas in Central and South America were under scrutiny by WHO consultants; the South-East Asia region, comprising India, Ceylon, Burma, Siam, and Afghanistan, was also being surveyed; and in the Eastern Mediterranean visits had been paid to Iran, Irak, Aden, Egypt, Transjordania, and other areas. Of all the factors entering into the spread of tuberculosis in most countries in the world the extent of infection and the low nutritional standards of the people were the two most naturally linked together. If there was no infection there was no tuberculosis, irrespective of the environmental standards of the community. The lower the nutritional and environmental standards and the greater the amount of infection the higher was the price to be paid in morbidity and mortality. Adequate nutrition was the most useful ally in this campaign, and without help from those directly responsible for world food supplies their efforts would be much less successful. The Expert Committee in its first report had said: "There can be no isolationism in the field of health. The fight against tuberculosis is not a national or racial problem it is a task for the whole of humanity."

Regional and Local Tuberculosis Schemes

From world problems the congress turned to discuss regional, county, and county borough tuberculosis schemes. Sir WILSON JAMESON (Chief Medical Officer, Ministry of Health) said that organized efforts to deal with tuberculosis dated only from 1912, or, more correctly, 1921, when the duty of making provision for the care of tuberculous patients was placed upon county and county borough authorities. With some outstanding exceptions, this provision was inadequate. Tuberculosis was not a disease which could be taken care of by general provision; it required special arrangements for prevention, control, and treatment, and various bodies had a part to play in it. The roots of tuberculosis lay deep in the conditions which favoured infection—bad housing, unhealthy industrial conditions, infected milk, malnutrition, and poverty, and unless all authorities did their duty there was no end to the road. They were apt to refer complacently to the great decline in mortality during the last few years, but the decline started long before any special attack was made, and in 1948 there were still nearly 22,000 deaths from tuberculosis in England and Wales, most of them at ages when the people should have been making their greatest contribution to the well-being of the community; and in the colonial empire it was the most widespread killing disease. The problem could be tackled only on sound epidemiological lines, with the isolation of infected persons, early diagnosis, and the management of subclinical infections.

The details of a tuberculosis scheme, Sir Wilson Jameson continued, were not to be found in the National Health Service

Act—they were a matter for local administration. To regional hospital boards was entrusted the institutional and dispensary part of the scheme, and to local authorities the arrangements for prevention, care, and aftercare. On the family doctor rested the responsibility for the preliminary diagnosis. He was a little weary of hearing complaints of confusion. Was anyone satisfied by the old arrangements under which the care of the tuberculous was isolated from all other branches of medicine? Anyone desiring now to specialize must undergo an extensive training and be eligible for consultant status if he made the grade, and it was only right that his employer should be the regional hospital board. But the preventive and social aspects of tuberculosis were more important than the curative, and the specialist who did not concern himself with all three would be failing in his duty.

The medical officer of health was the person to see that the community was getting the facilities it required and to secure the integration of the various parts of the scheme, one of which was the control of sources of infection. It was only by good will and common sense that a good service could be provided. The introduction of a new Health Service brought a new opportunity. They had better weapons than before to help them to overcome difficulties. What was wanted was a united and determined effort, and he hoped that this conference, held on the fiftieth birthday of the National Association, would mark a turning-point in the fight.

Bridging the Gaps

Dr. I. GREENWOOD WILSON (Cardiff) mourned the passing of the Welsh National Memorial Association. The area physician of that body had acted in every respect like the tuberculosis officer, sitting with the medical officer of health on committees and working in close collaboration with the local authorities. The average waiting-list for admission of Cardiff patients to association institutions over a period of years was 72, and the average time of waiting two to four months. Now the average waiting-list was 158 and the time of waiting three to nine months. The national administration had been split up between 14 hospital management committees. There was an echo of the medical committee in the advisory committee for each region which made recommendations to the regional hospital board, but an advisory body was not as powerful as an executive. There was a certain amount of weakness in an organization which divorced responsibility for institutional accommodation for the tuberculous from responsibility for their individual care. Dr. Wilson went on to describe what had already been done in Cardiff, and pointed out how much an active local authority could do for the care of patients and their families.

Dr. A. B. WILLIAMSON (Leeds Regional Hospital Board) said that the schism created by the Act between the clinical and preventive aspects soon became apparent, and the Board had sought ways and means of bridging the gap. Among these were a system of cross-representation, conferences between representatives of the Board and eleven health authorities, and on the professional side the formation of a technical advisory panel. Councillor G. E. HARDMAN (Withington Hospital Management Committee) said that the Lancashire County Council tuberculosis service had been a model of its kind, and he could not conceal the regret he felt at the break-up of one of the outstanding tuberculosis schemes in the country. He was left with the impression that they were going back in tuberculosis—not going forward. Mr. WILLIAM HARVEY (Northern Ireland Tuberculosis Authority) gave an outline of the Northern Ireland scheme, which was working well.

Dr. W. E. R. SAUNDERS (South-East Metropolitan Regional Board) said that the tuberculosis schemes of counties and county boroughs before the appointed day varied greatly in adequacy and efficiency. The smaller authorities had difficulty in providing a satisfactory service. Some of the larger authorities had much more satisfactory schemes, but even the L.C.C. scheme had two defects: that diagnosis was carried out by a number of metropolitan borough dispensaries while institutional treatment was the function of the county council itself, and that the tuberculosis officers, although carrying out their tuberculosis duties with great efficiency, had obtained their appointments with a view to becoming eventually medical officers of health of their respective metropolitan boroughs.

A discussion of the organization of comprehensive tuberculosis schemes in the Colonies was opened by Dr. CHARLES WILCOCKS (Director, Bureau of Hygiene and Tropical Diseases, London). He referred to B.C.G., a subject which must inevitably be considered wherever the tuberculosis situation was serious. B.C.G. was now being administered on a very large scale, and special teams were being sent by the World Health Organization to tropical and other countries.

Dr. R. B. MACGREGOR (Malaya), Dr. K. C. YEO (Hong Kong), Dr. W. S. HAYNES (Kenya), Dr. L. G. EDDEY (British Guiana), and Dr. P. C. COSGROVE (Sierra Leone), with others, gave accounts of the conditions and facilities in their respective fields.

Tuberculosis among Nurses and Students

A special session devoted to this subject was opened by Dr. JOHN LUNDQUIST (Stockholm). He said that during the last fifteen years special dispensaries for students had been set up in four Swedish cities, subsidized by the State and by the National Association. Students were regularly examined by tuberculin tests, *x* rays, and estimation of sedimentation rates. At first only first-year students were examined, but now older ones were included. It was considered important to examine them annually on account of the risk of infection to which they were exposed. A much higher morbidity occurred among medical students than among students from other faculties. Their long period of training might contribute towards this. At the beginning of their training medical students reacted negatively to about the same extent as other students, but in contrast to these others they often reacted positively during the third year, which coincided with the completion of the course in pathology. Among nurses tuberculosis was perhaps more prevalent than in any other profession. The death rate was six times greater among hospital personnel than among, for example, domestic science students. The disease was usually pulmonary, occurred during the first three years, and was caused by inhalation, often starting with acute laryngitis.

Dr. G. J. WHERRETT (Canadian Tuberculosis Association) said that this subject had received a great deal of attention in Canada during the last 25 years. In protecting the nurse the first step would appear to be the adoption of a rational nursing technique. In many hospitals there was a very casual approach to the question of infection in tuberculosis wards. Four essential points were: (1) adequate instruction of the nurses and students, and also of the patients; (2) care of the person, with adequate washing facilities; (3) protective clothing; (4) routine examination of all members of staff. B.C.G. vaccination had been found to be safe and had been generally accepted. Miss NORA BURROWS (N.A.P.T. Sanatorium, Matrons' Section) indicated some simple methods of prevention which should be carried out in all hospitals.

Dr. E. R. LONG (Pennsylvania) referred to the greatly increased incidence of tuberculosis among medical students as compared with other classes. It looked, he said, as if something happened during the second year, and the finger of suspicion was pointed more and more at the pathology course.

The discussion was wound up by Dr. MARC DANIELS (Medical Research Council). He said that for some reason people were apt to talk of infection in this disease as a useful method of immunization. In many hospitals a lack of elementary precautions, such as would be viewed with horror in wards for other contagious diseases, was tolerated. He referred particularly to the lack of instruction to new nurses or domestics entering the tuberculosis wards for the first time. This did not apply, of course, to the best hospitals, but it applied to many of the others. Infection could often be prevented by the wearing of masks, but these were used in relatively few institutions. Another method of preventing the disease among hospital workers was by the detection and proper treatment of the early lesion. Among nurses and medical students unparalleled opportunities for the early diagnosis of tuberculosis were often missed. There were still too few routine medical examinations in this country, especially when compared with the United States and with France and Holland. He added that he hoped the introduction of B.C.G. would not give people a false sense

of security. The vaccine did not provide complete protection, and the methods of maintaining resistance and avoiding hazardous exposure should still be applied. Recent work had shown that the major part of tuberculous infection was avoidable by taking adequate precautions, without detracting from the quality of the service given by hospital staff.

Administration of B.C.G.

The effectiveness of B.C.G. vaccine was debated at another session. Dr. K. A. JENSEN (University of Copenhagen) said that nearly thirty years had passed since B.C.G. was first employed for the vaccination of human beings, and discussions about whether it did any good were still proceeding. Experimentally it was ascertained long ago that B.C.G. vaccination increased the resistance of the organism but gave no absolute immunity. It would be unreasonable to expect more, for the resistance of experimental animals did not come up to the level of human resistance. Nevertheless, it was possible to ascertain some fundamental rules to which he wanted to call attention once more.

In the non-immunized organism the individual tubercle bacillus produced no toxic effects. It was phagocyted by one of the macrophages, in which it multiplied unhampered during the pre-allergic phase. But, once the state of allergy appeared, the tubercle bacillus exerted a strong influence, to which the organism responded with an acute exudative inflammation. At this juncture there were numerous tubercle bacilli present at the site of invasion, and there followed abscess formation with caseation—a typical primary focus. In the abscess itself the tubercle bacilli might keep on multiplying, whereas bacilli situated in the non-necrotic part of the inflammatory process were destroyed or ceased to multiply. Once a necrotic focus had developed there was danger of its spread.

In the immunized organism an acute exudative inflammation developed rapidly, but as a rule the irritant effect was not strong enough to give rise to a central abscess. Consequently the few tubercle bacilli remained embedded in reactive tissue and did not multiply, so that there was only a slight risk, or none at all, of the spreading of the process by endogenous aspiration or by way of lymphatics or blood vessels. Before long the exudative inflammation turned into chronic inflammation with a tendency to heal. But in the allergic organism the few tubercle bacilli might remain alive for a long time, and if resistance was lowered might multiply afresh. This illustrated the fundamental difference between the infection in immunized and non-immunized experimental animals, and there could hardly be any doubt that this great difference at the start of an infection might decide its later course.

The available experimental and clinical records on the effect of B.C.G. vaccine were now so comprehensive and reliable that they might properly wonder whether to-day it was justifiable to omit B.C.G. vaccination because controls were lacking. It remained to be seen whether B.C.G. vaccination would prove effective in countries where people were living under bad conditions, where natural resistance had been reduced because of malnutrition, and where the risk of exposure was grave.

B.C.G. Vaccination in India

Dr. P. V. BENJAMIN (Tuberculosis Association of India) said that B.C.G. vaccination was started in 1948 in India, where 4,000 clinics were needed and half a million beds, and at present there were only about 105 clinics and 7,500 beds. Vaccination had been in use for many years for small sections of the population, and the results showed that it could reduce considerably the morbidity and mortality rates, but where this had been the case the standard of living had been better than in India as a whole.

Vaccination of a few thousand people here and there could not materially change the trend in a country like India. It was estimated that 100 million people needed vaccination—people who were negative reactors, mostly in age groups below 20. One team of workers, consisting of doctor and nurse or health visitor, with other staff, and a mobile van, could vaccinate 100,000 persons a year. With 200 such teams it would be possible to vaccinate the whole population in five years. The vaccine was now prepared at a laboratory under the control of the Government of India and was certified by a number of experts. Six teams, each consisting of a doctor and two nurses, were supplied from Denmark and were now working in different centres in India. It was hoped by the end of 1950 to have trained about 200 teams.

Professor ARVID WALLGREN (Stockholm) said that there was no doubt that the number of people with natural resistance was increasing; in an isolated population the proportion would be small, but in an older civilization which had been fighting the disease for centuries it would be high. The degree of resistance was not fixed; it altered during the individual's lifetime with differences of nutrition, standards of living, and age. With B.C.G. vaccination the immunity lasted for five or ten years or more. It had been shown to last at least three years in 90% of cases, and six years in 80% of those examined. When sensitivity disappeared, re-vaccination should be undertaken if the risk of exposure continued. The object of this artificial immunity was to compensate for low natural resistance, and it was therefore particularly suitable for infants and small children, children at puberty, and those whose resistance was low owing to heredity or environment.

In addition to the formal sessions, clinical demonstrations were arranged at the Brompton Hospital, and there were visits to the Papworth Village Settlement, St. Mary's Hospital, Carshalton, the British Legion Village at Maidstone, and to Midhurst and other sanatoria. On the social side the delegates were entertained at receptions by the Government, by the British Medical Association, by the Royal College of Physicians, by the High Commissioner for India, and by the Wellcome Historical Medical Museum.

PROGRESS IN TREATMENT OF RHEUMATIC DISORDERS

INTERNATIONAL CONGRESS OF RHEUMATOLOGY

[FROM A SPECIAL CORRESPONDENT]

The Seventh International Congress on Rheumatic Diseases was recently held in New York under the joint auspices of the International League against Rheumatism and the American Rheumatism Association. The opening session at the Waldorf-Astoria was attended by over a thousand people, including some 300 rheumatologists from other countries. Messages from President Truman and Governor Dewey were read by the President, Professor Richard Freyberg. The paper by Drs. Hench, Kendall, Slocumb, and Polley, confirming officially the dramatic results which had been produced in severe rheumatoid arthritis by means of "cortisone" (Kendall)—compound E acetate—received an ovation such as is seldom seen at medical meetings. The effects described by these workers were confirmed by the five leading physicians who had each been provided with 1 gramme of the substance for trial. A brief summary of some of the more outstanding of the hundred papers read can be given by permission of the Congress authorities, who are publishing the proceedings in one volume later in the year (W. B. Saunders and Co.).

In addition to formal papers, a somewhat novel method of presentation was provided by "panel" discussions. Each panel was under the chairmanship of a distinguished physician, who had chosen five colleagues. For an hour they discussed the particular subject which had been allotted to them on the basis of specific questions submitted by outside members of the Congress the day previously. The official banquet was attended by high Governmental and medical personages, and afterwards the Honorary Membership of the American Rheumatism Association was presented to, among others, Lord Horder, Drs. C. W Buckley, W. S. C. Copeman, D. H. Collins, J. B. Burt, R. G Gordon, G. D. Kersley, W. Tegner, and Professor L. S. P Davidson.

Compound E

Drs. Hench, Kendall, and others reported that the adrenal cortical hormone 17-hydroxy-11-dehydrocorticosterone (compound E) had been administered to 16 patients with severe o

moderately severe rheumatoid arthritis. In each case improvement in clinical features and in sedimentation rates began to appear within a few days. When administration of the hormone was discontinued the disease generally relapsed promptly. Compound E has been given, with encouraging results, to three patients with acute rheumatic fever and to one patient with lupus erythematosus with polyarthritis. Essentially similar clinical results accompanied by various biochemical effects, including reduction of sedimentation rates, were obtained from the administration of the pituitary adrenocorticotropic hormone (ACTH) to four patients with rheumatoid arthritis.

The rarity of these compounds at present and in the immediate future, and the limited scope of the preliminary data (especially regarding prolonged administration), make inappropriate now the use of the term "treatment" except in an investigative sense. This paper was presented not as a clinico-therapeutic report but as a study of certain physiological effects which these new hormones exert on rheumatoid arthritis. To provide adequate controls the injections of the adrenal cortical hormone were in some cases preceded—in other cases replaced—by injections of a preparation of similar appearance, a suspension of cholesterol. The times when the control solution and the adrenal hormone were interchanged were unknown to the patients and were for five weeks unknown even to the three clinical workers who were evaluating the results. When injections of the control solution were first administered for a few days, no outstanding clinical or biochemical alterations occurred until these injections were replaced by injections of the hormone. Likewise, when the adrenal hormone was replaced by the control preparation articular and muscular symptoms recurred within a few days and sedimentation rates rose. The changes in the function of joints and muscles were also demonstrated by motion pictures taken before, during, and after the administration of the adrenal cortical or the pituitary adrenocorticotropic hormone.

After the Congress a few of the delegates visited the Mayo Clinic by invitation and were privileged to see a new series of cases of severe rheumatoid arthritis started on this compound. After only three days one stated that she was completely symptom-free, all objective tests being negative. At the end of a week all three appeared to be functionally normal and had remained so for several days after injections were stopped. The difficulty in synthesizing this substance, as well as the occasional occurrence of undesirable side-effects, however, ensure that it will not be available for anything but well-controlled experimental work for some time to come.

Pituitary-adrenal Function

Another paper of the highest importance dealt with the possible relationship of pituitary-adrenal function to rheumatoid arthritis. Its authors, Professor G. W. Thorn (of Harvard) and Drs. P. H. Forsham, J. E. Warren, and T. B. Bayles, reported that the pituitary adrenocorticotropic hormone (ACTH, Armour) in normal subjects and in patients with intact adrenals stimulates the secretion of electrolyte-regulating, carbohydrate-regulating, and androgenic adrenal steroids. A fall in the level of circulating eosinophils (direct determination) and an increase in the urinary excretion of uric acid represent sensitive indicators of the increased secretion of 11-oxy adrenal steroids. With the eosinophil change as a reflection of adrenal cortical function, patients with rheumatoid arthritis, rheumatic fever, and gout have been investigated by administering pituitary ACTH. The initial eosinophil level was found to provide a simple measure of adrenal cortical activity in selected instances. The response to ACTH is a semi-quantitative method of estimating the reserve capacity of the gland. Actions whereby adrenal steroids may modify the course of disease were discussed. Of particular interest is the fact that the pituitary-adrenal system serves as a link between the effect of psychological and emotional factors and measurable changes in metabolic processes.

Endocrines and Ageing of Tissues

Drs. Martin Silberberg and Ruth Silberberg spoke on the effect of endocrines on articular tissues and their relation to ageing processes. They reported that the growth processes and regressive changes occur spontaneously in the articular tissues of ageing mice. The changes manifest themselves in hyperplasia and hypertrophy as well as in destruction of the articular cartilage, outgrowth of bone, swelling or fibrinoid change of the interstitial substance of the ligaments, mucoid change or proliferation of the synovia, and fibrosis of the bone marrow. These age changes differ in different strains of mice; they are genetically determined as to their onset, incidence, and severity, and are controlled by endocrine secretions. Moreover, the course of these age changes may be influenced by nutritional factors. Administration of thyroid or sex hormones delays the time of appearance of the age changes in the articular tissues and decreases their incidence. Conversely, joint lesions can be produced in laboratory animals by the administration of anterior hypophyseal hormone or by removal of the sex glands. The changes thus produced are morphologically indistinguishable from those occurring spontaneously, although the former appear at an earlier age and are more frequent than the latter. Some data on the effects of certain nutritional factors on the articular tissues, in particular of a high fat diet, were integrated with the aforementioned findings. It seemed from the discussion which followed this paper that endocrine secretions may be involved not only in the pathogenesis of rheumatoid arthritis but also in certain types of degenerative joint disease.

New Work on Gout

Gout has been the subject of intensive study in the last few years, and there is now strong evidence of adrenocortical dysfunction as a controlling factor. An important paper was read by W. Q. Wolfson, R. Levine, C. Cohn, E. F. Rosenberg, H. D. Hunt, and H. S. Guterman, of Chicago, reporting their studies in this field. These seem to provide evidence for the existence of two types of adrenocortical dysfunction in gout.

1. In gout, biological androgen activity appears to be maintained by an abnormal male sex hormone which when metabolized contributes only slightly to urinary 17-ketosteroid excretion. Similar findings are not observed in non-gouty hyperuricaemia or in rheumatoid arthritis. This "gouty androgen" appears to originate in the adrenal cortex and to be secreted under the same conditions as normal androgen, and to be oestrogen-opposed. It appears probable that the normal sex differential in plasma urate concentration is controlled by normal androgen and that gouty hyperuricaemia is controlled by the "gouty androgen."

2. An acute relative adrenocortical hypofunction with respect to 11-oxysteroid production appears to provide the prodromal setting for the attack of acute gouty arthritis. This relative deficiency may result from endogenous cyclic metabolic changes, from increased peripheral demand for 11-oxysteroid due to certain varieties of stress, or from the withdrawal of adrenocorticotropin. Alterations in serum cholesterol concentration suggest that this prodromal relative deficiency of 11-oxysteroid secretion may be associated with increased production of other unidentified adrenal steroids. Spontaneous or induced increases in 11-oxysteroid production appear to tend to terminate the attack of acute gouty arthritis.

It appears reasonable to assume that production of an abnormal androgen by the adrenal and the deficient response of the gland to increased demand for 11-oxysteroid are not independent defects but two aspects of a single underlying metabolic disturbance in gout.

Another important paper amplifying and extending these fundamental observations came from Ann Arbor University, Michigan—the role of the anterior pituitary and adrenal cortex in urate metabolism and in gout, by W. D. Robinson, W. Conn, D. Block, H. Louis, and J. Katz. These endocrine factors have been studied by observing (1) the effect of adrenocorticotropic hormone (ACTH) on urate metabolism in normal and gouty patients and on the course of acute gout; (2) 17-ketosteroid excretion in gouty patients; (3) the effects on metabolism and clinical gout produced by stimulating the anterior pituitary with epinephrine; and (4) the effect of colchicine on the pituitary-adrenocortical mechanism. In addition to blood and urine urate determinations by a specific enzymatic method other indices of pituitary-adrenocortical activity were followed.

ACTH produces a marked increase in urate excretion in normal individuals, without a significant fall in blood ur The chief differences in a gouty patient given ACTH d

an asymptomatic period were a sharp decrease in true blood urate to less than 50% of the base-line levels and the absence of any evidence of rebound in pituitary-adrenocortical activity in the post-injection period; acute gout developed on the third post-injection day. Acute gout following tophectomy was not associated with any evident change in adrenocortical function. Injection of ACTH resulted in prompt temporary amelioration of symptoms on two occasions, and was followed by indications of adrenocortical stimulation. Epinephrine in doses of 1.5 mg. intravenously had no effect on acute gout. When it was given to an asymptomatic gout patient intravenously or intramuscularly in divided doses of 6 mg. daily, no metabolic effects were noted except a decrease in eosinophils. Twenty-six determinations of 17-ketosteroid excretion in 10 patients with gout gave values consistently lower than normal, during both attacks and interval periods. Colchicine in doses of 4 to 5 mg. orally and 2.0 mg. intravenously produced no change in eosinophil counts or nitrogen balance in patients with gout. Effects on blood and urine urate levels were inconsistent.

Tentative conclusions to date are (1) the adrenal cortex has a profound influence on urate metabolism; (2) its effect in gouty patients differs from that in normal subjects; (3) gout is characterized by a low excretion of 17-ketosteroids; (4) the adrenal cortex of gouty patients can respond to stimulation both during interval periods and at times of acute attacks. There is suggestive but not conclusive evidence that acute attacks tend to occur at times of decreased adrenocortical activity. Epinephrine appears to be an unsatisfactory method of stimulating pituitary-adrenocortical activity in gouty patients. The mode of action of colchicine through an endocrine mechanism has not yet been established.

Familial Gout

The familial aspects of gout were also reassessed in the light of modern knowledge by Professor J. H. Talbott. Gouty arthritis has long been identified as one of the diseases with a high familial incidence. Scudmore, in the first quarter of the nineteenth century, reported a paternal incidence of gout in 87% of patients who admitted a family history of this disease. Only recently, however, has the subject been studied as a genealogical problem with social and preventive implications. This has been possible in part because of the development of satisfactory methods for the determination of uric acid in serum. This in turn has permitted the accumulation of statistical data of the concentration of serum uric acid in the general population as well as in patients known to be suffering from gouty arthritis.

In the absence of certain obvious disturbances such as renal disease and leukaemia, etc., most non-gouty persons have a serum uric acid of less than 6 mg. per 100 ml., while gouty persons have a concentration above this level. The borderline between normal and gouty persons may be slightly lower in females than in males. Three series of gouty patients and non-affected relatives have been studied in recent years. These researches have been pursued in Ann Arbor, Cleveland, and Boston, respectively. The fourth series is now being investigated in Buffalo. The results are similar and the tentative conclusions significant. Approximately 25% of non-affected relatives of gouty patients have a hyperuricaemia when sampled at random ages. Presumably this percentage decreases in each decade of life, since an occasional non-affected relative with hyperuricaemia will develop gouty arthritis and will no longer be classified as a non-affected relative. The age at which hyperuricaemia appears has not been determined; possibly it is associated with puberty. The statistical evidence suggests that hyperuricaemia in gouty families is a single autosomal dominant gene. The mechanism whereby the dominant manifests itself is still uncertain. The strength of the dominant—i.e., the degree of elevation of serum uric acid—the duration of the metabolic dyscrasia, or an as yet unrecognized factor may each participate. As a problem in preventive medicine, or more appropriately anticipatory medicine, an enlightened approach to the care of gouty families would be the periodic examination of the serum of all relatives of gouty patients. These familial studies lend support to the hypothesis that the pathogenesis of gouty arthritis is related to an increased formation of uric acid by the body rather than to an impaired excretion.

Rheumatism a Social Problem

Dr. E. T. Conybeare, representing the British Ministry of Health, outlined the system on which it is proposed to tackle the problem of the rheumatic diseases under the National Health Service. He pointed out that the present reluctance of the medical staffs of a majority of the English teaching hospitals, and in particular of their specialist physicians, to accept rheumatology as a diagnostic and therapeutic specialty of proved value to patients and students may be regarded as the chief administrative difficulty in developing better medical care for rheumatic patients under the British National Health Service. The reasons for this attitude were discussed and suggestions made for the solution of the problem thereby presented. It appeared that in America professors of medicine were prepared to take the subject and its problems much more seriously, and considerable advances in knowledge had resulted.

Lord Horder spoke on "Rheumatism—A National Problem," and outlined the plan drawn up by the Empire Rheumatism Council to combat it. The dimensions of this problem, he said, were considerable. In Great Britain a conservative estimate of the number of adult sufferers from rheumatic disease is more than one million—or 1 in 50 of the population. The economic damage in sick pay, lost wages, and cost of treatment among the insured workers alone is £17,000,000 per annum, and this accounts for only one-third of the total population. An over-all figure of £30,000,000 would be a cautious estimate. Only by national action can this national problem be adequately dealt with. Health authorities should encourage and subsidize two types of rheumatic centres. (1) A specialized centre at a teaching hospital for diagnosis and treatment of cases referred by local centres, hospitals, or doctors; for teaching home therapy; investigation of new therapeutic methods; postgraduate courses of instruction and research. (2) Local (peripheral) treatment centres for out-patients referred by doctors. The result of such a plan would be to divide rheumatic patients into these groups: (*a*) a large section which with a very brief period of institutional treatment and a sound course of education would be enabled to carry on chiefly by simple home treatment, but would be kept under supervision by periodic visits to a treatment centre or by visits of skilled social service workers; (*b*) another large section which could secure adequate treatment, without much disturbance of normal life, by attendance for the necessary term at a local treatment centre; and (*c*) a smaller but important section which calls for treatment in hospital, rehabilitation, or for attendance at specialized treatment centres.

There is implicit in this plan the existence of some authority which would have the power to approve rheumatism clinics which satisfied the requirements deemed essential.

Rheumatoid Arthritis

Professor L. S. P. Davidson reported the results of a recent controlled investigation into the aetiology of rheumatoid arthritis by the Empire Rheumatism Council. In many previous published reports the absence of a controlled investigation into the incidence of similar factors in persons not suffering from rheumatoid arthritis makes it difficult or impossible to determine the validity of the aetiological claims made. The Scientific Advisory Committee of the Empire Rheumatism Council, believing that a properly controlled investigation into the aetiology of rheumatoid arthritis might provide clues indicating the most profitable direction for future fundamental laboratory studies, decided to devise a special method of case recording for statistical analysis which it was hoped would enable an answer to be given to some 20 aetiological questions. Five hundred cases of rheumatoid arthritis of five years' duration or less, and 500 control persons not suffering from rheumatoid arthritis comparable in regard to age, sex, and civil status, have been investigated and recorded. These records have been examined by the Council's statisticians, and the information from this investigation was summarized and will shortly be published in book form.

Dr. Charles Short, of Boston, and his colleagues presented a paper on the factors associated with the onset of rheumatoid arthritis—a statistical study of 293 patients and controls. His findings appeared to be on the whole more clear-cut

than those of the Empire Rheumatism Council. The onset of rheumatoid arthritis was usually preceded by constitutional symptoms or precipitating factors or both. Of the former the validity of fatigue and anorexia as prodromal symptoms was established. Strain, either mental or physical, and acute infections most commonly preceded the onset of arthritis, with, less frequently, exposure to cold or dampness, surgical operations, trauma, and childbirth. His data suggest that prodromal constitutional symptoms may mark the real onset, and that so-called precipitating factors merely determine a more easily recognizable phase, with articular localization of the morbid process.

The histopathology of rheumatoid arthritis, especially in the extra-articular manifestations, was discussed in a paper by Drs. Gibson and Kersley. They pointed out that further observations on synovial histology have confirmed that in early cases, before development of the Ghormley focus, diffuse plasma-cell reaction is present. By appropriate staining intra-cytoplasmic bodies, similar to those seen in myeloma, have been demonstrated in plasma cells; they are probably of protein nature. They pointed out that the nodules of rheumatoid arthritis can be clearly distinguished from those arising in rheumatic fever, though the pathology may not be dissimilar.

Other studies on the histopathology of the neuromuscular system in rheumatoid arthritis by L. Morrison, P. Catoggio, and Walter Bauer, of Boston, showed that small paravascular foci of round cells were present in the interstitial tissue of the nerves and muscles; these foci were usually in the perineurium or perimysium. The sympathetic chain was similarly affected by cellular infiltrations not only along the course of the fibres but also within the capsules of the ganglia as well. About 75% of the nerves and 65% of the muscles presented these cellular accumulations. In the muscles foci were found, whether blocks were taken from extensors or flexors, from the belly or near the tendon, from close to or far from an involved joint, from atrophied or healthy muscle. And similarly in nerves, whether motor or sensory or mixed, lesions were widely distributed. There was not much relationship between the presence of cellular accumulations on the one hand and, on the other, clinical activity of the disease, the age of the patient, and the duration of the disease. In comparing these nodular foci of round cells with those found in other disease of the connective tissue group like lupus erythematosus disseminatus, dermatomyositis, and rheumatic heart disease, it was concluded that no distinguishing diagnostic differences could be relied upon on account of overlapping pictures in the various diseases.

Further studies were presented from Sweden, America, and Chili on the electrophoretic analysis of plasma proteins, the urinary excretion of amino-acids, and a differential sheep-cell agglutination test for rheumatoid arthritis. Dr. E. G. L. Bywaters reported a "palindromic" variant of rheumatoid arthritis, from which he concluded that the separation of cases of "palindromic rheumatism" from the main body of rheumatoid arthritis may be justified on prognostic and therapeutic grounds, but that from the nosologic point of view, until further information is available about the causation of this group of diseases, we should view this type of case as a variant from the main type of rheumatoid arthritis.

Gold and Copper

The Department of Medical Physics of California University (Dr. J. J. Bertrand *et al.*) reported on the distribution of radioactive gold in the blood of animals and man. They stated that relatively small amounts of gold are held by the blood cells, the white cells containing much more per unit weight than the red cells. Most of the gold is found to be in the plasma and in a form which is chemically bound to one or several of the plasma fractions. It has been repeatedly demonstrated that soon after the intravenous injection of gold sodium thiosulphate it is present in the plasma in a form that will not dialyse through a semi-permeable membrane. At the present time work is under way by which the one or more fractions of plasma proteins which contain the gold may be identified. Dr. L. Grauirer (New York) described successful results in 8 cases of rheumatoid arthritis where gold had failed, by means of post-partum plasma, administered over a period of a year. Drs. J. Forestier, A. Certonciny, and F. Jacqueline from an experience of over 300 cases consider the indications for injections of copper salts to be as follows: (*a*) early cases of rheumatoid arthritis, where the action is quicker than that of gold salts; (*b*) resistance to gold salts (dubious results); (*c*) intolerance to gold salts (favourable results); (*d*) psoriasis arthropatica, polyarticular synovitis with effusion, and certain forms of chronic polyarticular gout. In cases where gold is tolerated, however, this substance remains the better of the two.

Ankylosing Spondylitis

Drs. Roland Davidson and Koetz, of Stanford University, California, read an interesting paper on the effect of △ 5 pregnenolone on urinary 17-ketosteroid excretion and on the symptomatology of ankylosing spondylarthritis, with a note on the results of fractionation. They report that increased urinary excretion of 17-ketosteroids has been demonstrated in ankylosing spondylarthritis in both male and female patients, and is present in early cases with little demonstrable joint change as well as in those patients who have had the disease for many years and show the typical findings of the advanced case. △ 5 pregnenolone is a steroid having several actions not characteristic of other steroids. Its chemical composition makes it a logical process material to act as a precursor of many active steroids. When normal individuals are subjected to acute stress and fatigue adrenal cortical activity is accelerated and increased rates of 17-ketosteroid excretion are observed. Pregnenolone administered under such conditions lowers the 17-kestosteroid excretion, improves performance, and combats fatigue. This steroid has not previously, they believe, been used in disease states. Its general properties, freedom from toxicity, its ability to lower urinary 17-ketosteroid excretion and to combat fatigue suggested its possible value in spondylarthritis.

Two series of cases treated by deep *x*-ray therapy were then assessed. The Canadian workers D. C. Graham, A. A. Fletcher, and Wallace Graham reported that 60% of cases received some symptomatic benefit, but they could find no evidence that the underlying disease process is affected. Severe reactions were rare, but one case developed a fatal leukaemia. Drs. F. Foster and J. Gillespie, of Boston, on the other hand, considered that in some at least of their cases the disease process had been rendered inactive, and in 88% they claimed favourable effects —more particularly in those cases treated within ten years of onset.

An important contribution to our knowledge of the role of heredity in both spondylitis and rheumatoid arthritis (these entities tend to be confused in many American statistics) was made by Drs. Robert Stecher, W. Solomon, and R. Wolpan, of Cleveland. The heredity and familial incidence of rheumatoid arthritis and spondylitis was studied by comparing the family history of patients with rheumatoid arthritis and of spondylitis with each other and with the families of several control series. Rheumatoid arthritis occurred in the fathers, mothers, and sisters of rheumatoid arthritis patients in a significantly higher proportion than it did in the relatives of patients with spondylitis or in the controls. Spondylitis occurred in the brothers and sisters of spondylitis patients and of rheumatoid arthritis patients more than it did in any other group. The figures, which had been statistically analysed and shown to be significant, were striking.

Non-articular Rheumatism

Dr. Henrick Seyfforth, of Oslo, presented a paper on the disease picture presented by chronic overstrain of the skeletal system as the result of faulty posture, occupational stresses, etc., reviewing the whole field from the angle of industrial medicine.

Dr. W. S. C. Copeman illustrated his paper on "the relationship of fibro-fatty tissue changes to certain rheumatic syndromes" with a film-strip. He showed that a completely new pathological entity appears to underly certain of these conditions, which in essence consist of a periodical shift of body fluid accompanied by tension pain. This is probably

under endocrine control, and in its later stages may give rise to actual herniation of the affected fat tissue in certain locations. Dr. O. Steinbrocker, of New York, spoke on reflex dystrophy of the extremities, basing his remarks upon a study of 98 cases, some of which he had followed up for ten years. He considered that stellate ganglion block is the most rapid therapeutic measure in such cases.

The fashionable "psychogenic" conception of certain forms of rheumatism was discussed in four major papers, the most broadly based of which was that of Dr. W. Tegner. He reviewed the problem from the standpoint of general medicine. He said that, though fundamentally the syndrome is present without physical signs of organic disease, there are many reactions which can be elicited which are of help in establishing the diagnosis. Laboratory findings and radiological examination will assist in excluding organic disease. The nature of the sensations of which the patients complain is abstruse and of great interest. It is very personal to the individual patient. The value of physiotherapy, which is so often ordered, is open to debate. The response of patients to various forms of treatment may be so bizarre as to be of diagnostic significance. The disposal of these patients presents a real problem. They are a burden to the community. Their symptoms are of value to them and are not easily dispelled. Individual psychiatry is not normally possible or helpful. Experimental work on group therapy is being carried out.

Drs. A. Walters, Wallace Graham, and H. C. Slade, of Toronto, reported that as the result of a clinical study of cases of this type they conclude that fibrositis may be a mixed entity. Factors influencing this appear to include both peripheral physical faults and central psychological abnormalities. Dr. E. Weiss, of Philadelphia, stressed the unsuspected physical causes such as brucellosis and subacute rheumatic fever which may underly the diagnosis of fibrositis. He considers, however, that a similar picture can arise solely from mental causes, of which marital problems are the most common. Dr. A. Ludwig, of New York, reported a small group of similar cases in which psycho-analysis had demonstrated a characteristic personality structure.

In the pathological sections there were several papers of interest and importance. Those on various aspects of connective tissue pathology—the key to our basic understanding of the rheumatic diseases—were contributed by such authorities as Karl Meyer and Paul Klemperer (New York) and Marian Ropes (Boston). The role of enzymes in rheumatic disease, the histological and chemical changes in skeletal muscle in normal and rheumatic subjects (J. J. Bunim *et al.*), and some new work on cardiac changes induced by certain types of streptococcus (Homer F. Swift) all attracted considerable attention, as did Dr. Douglas Collins's paper on the range of pathological reactions which can be displayed by human synovial tissues—a contribution to the study of specific lesions in which he stressed the need for caution in comparing reactions in synovial and extra-articular tissues. Dr. L. Dienes, of Boston, put forward some further work on the possible relationship of pleuro-pneumonia-like organisms to articular disease. J. H. Kellgren's address on the peripheral genesis of pain, in which he put forward new work on the many different mechanisms involved, was also the object of much interest.

After the Congress

Subsequent to the Congress in New York a party of delegates attended the American Medical Association's Annual Meeting in Atlantic City, where they listened with interest to the denunciation of "socialized medicine" contained in the presidential address which was given before nearly 12,000 medical men and women. After this they were taken on a post-convention tour to some of the chief centres of rheumatic research work. They visited Philadelphia, where they were guests of the American College of Physicians, as also of the University. From there to Boston, where the Massachusetts General Hospital, Robert B. Brigham Hospital, and other famous institutions, including Harvard University, provided scientific sessions and entertainment. The Niagara Falls and the University of Buffalo were visited *en route* (by lake steamer) to Detroit and Ann Arbor University. Next came Chicago and a fascinating practical demonstration of the effects of adrenocortical steroids on both rheumatoid arthritis and gout. From Chicago to the Middle West, to Rochester, Minnesota, where the party were hospitably entertained for three days at the Mayo Clinic under the auspices of Drs. Hench and Kendall. Some delegates remained for another week to study further work in the Rheumatism Department while most of the party proceeded to Washington. Here the heat-wave began to "get down" even the tougher delegates, and the party returned to New York after two interesting days there. The proceedings were marred by the sudden death of the president of the Congress, Professor Ralph Pemberton, whose loss will be widely felt. Dr. Loring Swaim, of Boston, deputized for him throughout.

MATERNITY AND CHILD WELFARE CONFERENCE

Effects of Legislation on Mothers and Children

The annual conference of the National Association for Maternity and Child Welfare was held at Friends' House, London, from June 22 to 24. The general theme of the six sessions was the effects of recent social legislation on mothers and children.

The conference was opened by Dr. CHARLES HILL, Secretary of the British Medical Association, who suggested that the experts in the field of social welfare and legislation were confronted with certain dangers. They were tempted, when reading the recent report of the Royal Commission on Population, to speak of potential mothers as "women of child-bearing age," and to think of children as "contributions to a population policy, also as recipients of calories, as vehicles of infectious disease, as temporary possessors of tonsils, and as a form of biological life worthy of the deepest scientific study by those of reforming mind." He was sufficiently "impertinent" to present a purely parental point of view, and, undismayed by the collection of distinguished obstetricians, administrators, and educationists he saw in front of him, to plead for an emphasis on a field of responsibility which no others could assume—namely, the responsibility which must be placed fairly and squarely on the shoulders of parents.

There was a danger, said Dr. Hill, that there might be handed over to external authority something which belonged to the parent, a danger also that, in tackling the complexities of legislation and struggling with the intricacies of administration, the simplest lessons of all might be forgotten—namely, the need for bringing home to the people—what was the secret of any population policy—that there was far more satisfaction to be found in the humdrum rearing of a family than in all the external delights which civilization had imported into this modern age.

The General-Practitioner Obstetrician and the Midwife

In the first discussion, with Sir ALLEN DALEY presiding, the opener was Dr. E. K. MACDONALD, medical officer of health for Leicester. He discussed the problem arising out of Section 23 of the National Health Service Act—of the provision by local health authorities of a midwifery service. The problem was in the relationship of the general-practitioner obstetrician and the midwife. In theory there was everything to be said for the establishment of a class of general practitioners with special experience and knowledge of midwifery, who would stand at the side of the midwife ready to help when help was needed. But the Ministry's regulations were drawn so loosely and presupposed so low a minimal standard of service for quite good remuneration that at times the patient must suffer. Dr. Macdonald referred in particular to the requirement that the general-practitioner obstetrician must give a minimum of two antenatal examinations. Did anyone feel that this was adequate? The danger was that a few general-practitioner obstetricians might be content with this low standard and, feeling it to be adequate, might not permit the midwife to do antenatal work herself, while the more conscientious practitioners, who were, of course, in the majority, would themselves

carry out a complete service of antenatal care and again exclude the midwife, whose experience would suffer.

While he welcomed the genus general-practitioner obstetrician, he felt strongly that its numbers should be restricted to practitioners who had had real experience and special training in the specialty, and that the principle of the doctor undertaking the confinement so that he might retain the remainder of the family on his list should be forgotten. He added that in Leicester there were some 2,500 domiciliary births a year and 100 general practitioners—giving an average of 25 cases, among which there would be very few "abnormals." Sufficient experience to deal with a bad abnormality could not be gained by that method, and what he would prefer was only 20 general-practitioner obstetricians, who would do all the abnormal domiciliary midwifery in the city.

Dr. BARBARA BAILEY, who continued the discussion from the point of view of a general practitioner, said that the new maternity service had been the cause of some heartburning among doctors and midwives. The difficulty arose over the question of attendance at confinement. The patient usually wanted the doctor to be there when her baby was born, because, rightly or wrongly, the question of the doctor attending the confinement was wrapped up in the patient's mind with the relief of pain. The midwife, who should be, in the words of the Working Party's report, the "practitioner of normal midwifery," felt herself relegated permanently to the position of maternity nurse. The doctor was pulled all ways—by the patient who pressed him to attend her confinement whether necessary or not, by the knowledge that he was not intended to oust the midwife from delivering the normal case, and by the feeling that attendance at a certain number of normal confinements was absolutely necessary to maintain skill and clinical judgment. It was difficult to see how the balance could be struck and good feeling maintained between midwives and doctors; yet it was vitally important that there should be good feeling in the interests of the mothers and babies. It was her own practice to be present at the majority of the confinements of her National Health Service patients, to ask the midwife to deliver the baby and herself to be responsible for the analgesia and anaesthesia as required.

In Middlesex, out of 2,760 confinements occurring during the first nine months of the new Service, a doctor attended in 2,197 cases—an astonishingly high record. These figures showed that the doctors had set themselves a more exacting standard of work than the Act required. The statutory number of antenatal examinations was insufficient. Her own experience showed that eight antenatal examinations were made of each patient; she would regard it as a retrograde step if she saw a patient only twice during pregnancy. Yet that was all that was required by the terms of the Act.

Safeguards for Mother and Child

The Minister of Health was expected to address the final session of the conference, but his place was taken by Mr. A. BLENKINSOP, M.P., Parliamentary Secretary to the Ministry. Mr. Blenkinsop also devoted some part of his remarks to the maternity medical service. In this respect, he said, Scotland had for some time past been a pioneer in the use of doctors in domiciliary confinements. It was hoped to secure a further advance by ensuring that if a doctor was needed by a midwife at the time of the confinement he should be one already conversant with the case he was handling. This would be an additional safeguard both for mother and child. But it was certainly not intended to take away the midwife's feeling of responsibility. It was felt that there was a great opportunity for partnership between midwife and doctor for the benefit of mother and child. The clinic and the centre had a great part still to play, and here again it was certainly not desired to see any diminution of the vital work the clinics had to carry out. There was room for much voluntary work in antenatal supervision, advice on diet, and education for motherhood. The Ministry desired to see the most effective co-operation between doctor, midwife, clinic, and health visitor. This meant that there must be close liaison between the regional hospital boards, the local health authorities, and the executive councils. Mr. Blenkinsop concluded with some remarks on vaccination and immunization. The Ministry was concerned at the fall in the percentage of children vaccinated since the ending of compulsory vaccination. Recent events had underlined the importance of taking proper precautions early. With rapid modern transport there still might occur small outbreaks of smallpox which caused a great deal of worry and concern to large numbers of people.

In reply to a remark by a member of the audience that, while a great deal of lip-service was paid to maternity and child welfare, medical officers were being driven out of the service owing to the salaries offered, Mr. Blenkinsop said that he could not enter into a discussion on the salaries of medical officers of health. He gathered that the medical officers had put in a claim; he was afraid a great many other people were putting in claims at the moment.

Nova et Vetera

HISTORY OF A SPECIALTY

A History of Oto-Laryngology. By R. Scott Stevenson, M.D., F.R.C.S.Ed., and Douglas Guthrie, M.D., F.R.C.S.Ed. (Pp. 155; illustrated. 17s. 6d.) Edinburgh: E. and S. Livingstone. 1949.

The compilation of a history of even a small section of medicine entails a great deal of reading, with separation of the relevant from the irrelevant. In this discrimination the authors have fully succeeded, and they have reviewed references as far back as 3500 B.C.

It is clear that no real advances in the study of the ear, nose, and throat could take place until anatomy was taken seriously, as it was in the sixteenth century with the studies of Vesalius, Leonardo da Vinci, Eustachius, and Fallopius. The seventeenth and eighteenth centuries saw such important workers as Willis, who showed that the seventh nerve was different from the eighth; Valsalva, who observed fixation of the stapes in the oval window; and Scarpa, who described the saccule and utricle in 1789. All these discoveries were remarkable in the absence of modern aids to research. In the nineteenth century, when otology became a science, a galaxy of talented observers arose from all parts of the world. There was Helmholtz in 1862, with his "Sensations of Tone"; Flourens in 1830, and his work on the semicircular canals; Breuer in 1874, who noted that rotation caused movements of the head in animals and nystagmus in men; and that trio, Weber, Rinne, and Schwabach, whose names are still applied to tests to-day. Though a quack, Curtis made a fortune and founded what became the Royal Ear Hospital; he died in poverty

After an account of these workers comes the story of James Yearsley, Toynbee, who was aural surgeon to St. Mary's Hospital (which has the distinction of being the first general hospital to allot beds to the specialty), and Sir William Wilde, of Dublin. There follows an interesting chapter on the education of the deaf down the years.

It is a matter of interest that laryngology did not progress at the pace of otology, but once established it went ahead rapidly. Though Garcia is hailed as the founder of laryngology (he saw his own cords by means of mirrors in 1855) it is satisfactory to read that Benjamin Guy Babington is credited with the invention of his "glottiscope" in 1829, though the authors throw doubt on his having seen the vocal cords. Physick, of Philadelphia, is named the father of American surgery; in 1820 he published an account of his method of removing tonsils by means of a snare, suggesting this was original. The modern sections are crowded with the names of well-known figures, many of whom will be known in person by readers.

This is a most readable volume of great interest to ear-nose-and-throat surgeons, and indeed to all those who enjoy medical history.

W. M. MOLLISON.

The *Daily Telegraph* (July 1) reports that Lloyd's underwriters will now insure anyone against contracting certain infectious diseases. This is a development of a scheme introduced during the epidemic of poliomyelitis in 1947.

ONE HUNDRED AND SEVENTEENTH ANNUAL MEETING

of the

British Medical Association

HARROGATE, JUNE 28 TO JULY 1, 1949

THE SECTIONS

SUMMARY OF PROCEEDINGS

In subsequent issues there will be printed in the BRITISH MEDICAL JOURNAL *a few of the opening papers read at the Scientific Sections. All the papers will be published in full in a separate volume of Proceedings. The reports of the discussions, concluded in this issue, are intended to give members who were not present a general idea of the proceedings.*

SECTION OF ANATOMY

Tuesday, June 28

Structure and Function of Muscle

With Professor JOHN KIRK (London), the president, in the chair, Professor W. T. ASTBURY (Leeds) opened the discussion on the structure and function of muscle by considering muscle as a molecular machine. Studies of muscle protein by *x*-ray diffraction analysis had shown that pure myosin had essentially the same structure as whole muscle itself, and that molecules of myosin were oriented in the direction of the myofibrils. Myosin seemed to be the seat of the contractile properties of muscle. Closely similar diffraction pictures were given by keratin of hair or wool, so that these molecules appeared to belong to the same family of elastic proteins. Recent work, too, had shown that the protein of bacterial flagella had a similar structure. The essential characteristic of all these proteins was that they could alter their molecular length and form. Even in the resting relaxed state they were in a folded configuration, but they could be pulled out into a more extended form or become more folded still. The molecules in india-rubber were somewhat different in that they were ordinarily coiled up in a complex manner, though they too could be pulled out into a chainlike form. The folding of hair and muscle protein was more regular than in the case of rubber. It was possible to make the protein of hair supercontractile so that a hair might contract to half its ordinary length. It would seem then that the basis of elasticity of hair, muscle, and india-rubber was essentially the same—a straightening out of already folded-up molecular chains with the resumption of the initial state when the extending force was removed. Professor Astbury showed electron photomicrographs of myofibrils which he had recently received from Draper and Hodge in Australia. Such work suggested that actual shortening of the contractile elements of the myofibril took place at the molecular level, and thus was not to be observed with the electron microscope but only by the indirect method of *x*-ray diffraction analysis.

Although myosin was now believed to be the actual substance which became shortened at the molecular level during muscular contraction, the work of Szent Györgyi and his colleagues had shown that there was another contractile protein present in muscle—"actin." That, too, could be prepared pure and studied by the electron microscope and by diffraction analysis. Actin could exist in a corpuscular form as a series of discrete rounded particles, and also assume a fibrous form by the joining together of these elementary bodies. This change was reversible, and could be brought about by alterations in the *p*H or salt concentration of the dispersion medium. The modern view was that myosin and actin worked together in the shortening of the myofibrils. The globular (corpuscular) form of actin became converted into the chainlike filamentous form, and contracted (i.e., more folded) molecules of myosin ranged themselves alongside these filaments.

Electron microscopy with the replica technique and the method of stripping successive layers developed in the Leeds school had shown that the cross striation of the myofibrils was real enough, though the surface of the fibril opposite striations was raised, which suggested differential changes during the dehydration necessary in preparing material for electron-microscope examination. In addition to the ordinary bands there were transverse striations some 400 Å apart which might be due to local accumulations of calcium and magnesium. These bands had been studied further by micro-incineration coupled with electron microscopy. Ordinary muscle striations were not essential for muscular contraction; they were not, for example, seen in plain muscle. Their appearance was associated with the need for speed of contraction. Striations might be depots of essential materials such as calcium or magnesium placed ready for use, as barrels of tar might be ranged along the side of a road under repair. Such stores might be used up if the muscle were worked too hard, and indeed an overworked muscle did show fuzziness and displacement of the striations. The flagella of *Proteus vulgaris* were made up of macromolecules; photographs indicated a structure similar to that of myosin. Flagella were probably macromolecular hairs—the simplest possible unit. Those flagella were thinner than the rods of the tobacco mosaic virus—probably about 120 Å against the latter's 150 Å.

Dr. R. BARER (Oxford) said that the sarcoplasm of muscle fibre would escape as a jet through a rupture in the sarcolemma, and the clear fragment of membrane remaining could then be examined with the electron microscope. Minute circular dots appeared on it, but their nature was unknown. The sarcolemma was less than 0.1μ thick. Very fine collagen fibres were closely adherent to the surface of the membrane and could readily give rise to mistaken ideas about the structure of the sarcolemma if examined by the progressive stripping technique of the Leeds workers. The sarcolemma had considerable elastic strength. The old idea of Kühne that sarcoplasm itself was contractile could not be entirely dismissed. There always remained the problem of how the nervous impulse brought in at the motor end-plate was disseminated to the myofibrils. Phase-contrast microscopy suggested that the incoming nerve fibre might lose itself in the granular sarcoplasm. The myofibrils were 1–2 μ in diameter. When a muscle fibre was treated with alkaline Ringer solution the myofibrillar contraction became asynchronous, and it was then possible to study the individual fibrils.

Professor W. E. LE GROS CLARK (Oxford) said that the experiences of the war had started an investigation into the vascular pattern of different muscles from the point of view of its influence on the prospects of regeneration or survival after injury. Each muscle seemed to have its own vascular pattern. Although it would seem possible that there might be anastomoses within the muscle, injection preparations suggested that was not the case, for the anastomoses were inadequate to carry on the nutrition of any devascularized area. The tibialis anterior muscle was supplied entirely from the anterior tibial artery and was therefore more susceptible to necrosis than extensor digitorum longus or extensor hallucis longus, which received branches from the posterior tibial artery also. In a second type of vascular supply a single branch entered a muscle or a muscle belly. That was seen in the two heads of the gastrocnemius muscle, where such single branches formed virtually the whole blood supply. On that account the muscle was susceptible to necrosis. Similarly, the biceps was also liable to have its blood supply interfered with, and a case of necrosis limited to that muscle was on record.

Individual branches within a muscle might anastomose, but such anastomosis might not be adequate for continued nutrition of the muscle. It was possible that in extensive incisions into muscles carried out at operation there might result more extensive necrosis than was commonly supposed. However, muscle was able to undergo considerable regeneration—

surprising amounts of regeneration in view of the commonly held view that muscle healed by scar tissue. By producing vascular lesions and examining the partially devascularized muscle at intervals after the operation he had shown that the necrotic area, which was found after two days, was invaded in about three weeks by streams of nucleated protoplasm growing down from the uninjured muscle fibres. It was astonishing to find that in the rabbit the greater part of the tibialis anterior muscle could be replaced in that way. The empty endomysial sheaths acted as guiding channels for the protoplasmic strands in much the same way as Schwann sheaths guided regenerating nerve fibres. It would appear that protoplasm might grow out with equal vigour from both ends of a muscle fibre. However, if scar tissue became interposed in the path of the outgrowing protoplasmic strands, then they became blocked and swelled up into pools, like neuromata. In one of Dr. F. K. Sanders's preparations of regenerating nerve, regenerating muscle fibres coursed down endoneural tubes. That would suggest that it was the mechanical action of the tubes acting as guides rather than any special chemotaxis which aided the regeneration of the muscle fibres. Possibly the areas of hyaline degeneration occurring in certain muscles in the course of such diseases as typhoid fever might disappear by regenerative processes such as those described.

Dr. R. E. M. BOWDEN (London) described the histological changes taking place in human voluntary muscle at intervals after peripheral nerve injury. After six weeks there was a certain looseness of the muscle fibres, which also had a tortuous appearance. Nuclei tended to become crowded together and the myofibrils were prominent. There was increase in fat and connective tissue, but there was no fat *within* muscle fibres, nor did there appear to be fibrous metaplasia of muscle tissue. Even 26 years after denervation there were still "ghosts" of muscle fibres to be seen. Motor end-plates could be recognized up to nine months after division of a peripheral motor nerve. Blood vessels in the muscle changed, the intima and media becoming thickened and perivascular leucocytic infiltrations appearing. In a favourable type of nerve injury with preserved Schwann tubes nerve fibres could be found struggling across fibrous tissue towards the original motor end-plates when regeneration was taking place, a finding in agreement with the experimental work of Young and Guttman on the possible regeneration of motor end-plates.

As to electromyographic changes shown by denervated human muscle, fibrillation action potentials began to appear 10 days to 4 weeks after denervation. Fibrillation potentials might make their appearance only on attempting voluntary movement. It seemed that the higher a nerve lesion the more rapid the rate of recovery—a finding in accordance with Young's theory of an axonic *vis a tergo* from the cell body being the basis of nerve-fibre regeneration.

Mr. W. F. FLOYD (London) said that fibrillation action potentials seemed to be the units of which ordinary activity was made up. The latter was due to random temporal distribution—i.e., an asynchronous firing-off of the individual motor units. It had to be remembered always that the electrical disturbance was over when the actual wave of muscular contraction took place. The introduction of the needle electrode into a muscle led to a burst of electrical activity—"insertion potentials"—ordinarily of very short duration, but in cases of myotonia atrophica it might last two seconds or more. Tapping a muscle also caused an outburst of electrical activity, which again was prolonged in myotonia. In that condition, too, gentle palpation of a muscle had the same effect. Characteristically, there was a persistence of action potentials after the cessation of stimulation, and that persistence might go on for three or four seconds. The phenomena were not made to disappear by curare. The disease could not, therefore, be one which affected the motor end-plate. It had been found than intravenous procaine modified greatly the myototic response of myotonic muscles.

In the discussion which followed cases were alluded to in which muscular spasm was unaccompanied by any electrical record. It was also pointed out that in the case of heart muscle the electrical manifestations did not necessarily parallel the degree of muscular contraction.

SECTION OF MEDICINE

Thursday, June 30

Streptomycin

With the vice-president, Professor H. W. FULLERTON (Aberdeen) in the chair, Dr. GEOFFREY MARSHALL (London) read a paper on streptomycin. In cases of tuberculous meningitis the drug had been given intrathecally and intramuscularly daily for one month, after which an interval of a week was allowed. This was followed by 48-hourly dosage, continued for at least three months and probably six months. As a result 30% of the children over the age of 3 had been cured; many had survived for a period, maimed either by deafness, blindness, or paresis, but most of these patients had died within a year. In only three cases had resistant strains of tubercle bacilli developed.

There had been fashions in the treatment of pulmonary tuberculosis. They had shown how difficult it was to assess results in this disease. Controls were necessary. It was decided to use streptomycin in patients between the ages of 15 and 30 in whom the disease was of not more than 12 months' duration and of exudative type, where cavitation was not the dominant feature, whose sputum was positive, and pyrexia was present. The cases and controls were selected by a statistician with the usual precautions. Some patients died during the period of observation and were therefore omitted from the series, which left 55 treated cases and 52 controls. The treatment lasted four months and was followed by two months' observation. As a result 69% of the treated cases were improved, against 33% of the controls. He emphasized how well some of the controls had done. They had become apyrexial and even put on a stone in weight. Of the treated patients 7% died during the period of observation, of the controls 27%.

There appeared to be two disadvantages: first, the development of resistant strains of tubercle bacilli, and secondly the effect of the drug on the vestibular mechanism of the body, producing ataxia. In non-tuberculous disease of the lung the drug was particularly effective against *Ps. pyocyanea*, but unfortunately resistance developed within a very short time.

Professor ROBERT CRUICKSHANK (London) said that using the drug had caused the development of more accurate methods for the demonstration of the tubercle bacillus and estimating its sensitivity to streptomycin. The examination of smears was inadequate, and culture had become essential. To achieve this it was necessary to render the sputum homogeneous and to kill other organisms that might be present. The usual method of doing this involved treatment with N/1 NaOH for 20–30 minutes at 37° C. But this was not very satisfactory, since many tubercle bacilli were killed with the other organisms. The method known as Jungmann's acid-iron-peroxide method was the best.

With regard to medium, if egg was used it should be made from fresh eggs and must be sown within three months. The du Boss medium, made with bovine albumin, which protected the tubercle bacillus, was most effective, and it could be made into a solid plate by the addition of agar. It might even render homogenization unnecessary, since penicillin and sulphonamides could be incorporated to prevent the growth of secondary organisms. He hoped that fungicides might also be added. A rapid test of sensitivity could be developed by sowing two plates, one as already described and the other containing streptomycin.

Strains that became highly resistant were in patients who had a poor tissue resistance and invariably did badly. The degree of resistance therefore could be used to some extent in assessing the prognosis. Low chloride in the cerebrospinal fluid was not of value in determining the early stage of meningitis, but on the other hand the sugar value was of great importance; in no case was it found above 50 mg. per 100 ml. In non-tuberculous disease the drug had been most effective in cases of *H. influenzae* meningitis, but all organisms became very rapidly resistant.

Dr. KENNETH PERRY (London) referred to the use of streptomycin in thoracoplasty. Started three days before the operation, it had not proved a very successful umbrella in

preventing spread of infection, though it was most effective in treating it. The optimum time for inducing an artificial pneumothorax for the purpose of closing cavities in the more acute case was three or four weeks after the start of streptomycin therapy.

Dr. MARSHALL, replying to questions, said that he considered the use of streptomycin in clear pleural effusion was wrong, since there was no method of determining which might subsequently develop pulmonary tuberculosis or indeed which were tuberculous; and, further, its use would be likely to produce resistant pulmonary disease. It was found to be not as effective when inhaled as when injected intramuscularly. It had not proved very effective in the treatment of pyothorax, though it was very good when the Semb space was infected.

Radioactive Substances

Dr. R. R. BOMFORD (London) then took the chair, and Dr. RUSSELL FRASER (London) read a paper on radioactive isotopes. These were most useful at present in physiology and experimental medicine, where they could be used for tagging substances either given by mouth or injected intravenously, so that they could be traced through the body. It must be remembered that the patient was given irradiation, and the proper protection was necessary. No patient was given more than 0.01 r in a day. This was quite safe; 25 r was given in a local exposure when a barium meal was performed. Some isotopes were more useful than others. Calcium could not be used, because of its long half-life; conversely, the rays of nitrogen were soft and its half-life was very short. Radioactive iodine was one of the best, since its half-life of eight days was not too long to be dangerous and not so short that it could not be measured.

Isotopes could be used in treatment. Many thyroid cancers did not concentrate iodine, but several did. In the latter radiation could be given to the right place in greater concentration than by any other method. Radioactive phosphorus was very effective in the treatment of chronic leukaemias and polycythaemia. Isotopes might also be given in insoluble materials for the local treatment of accessible carcinomata such as those of the breast.

In diagnosis radioactive iodine could be most useful in showing whether or not a retrosternal tumour concentrated iodine, and so whether or not it was a retrosternal goitre.

To aid the diagnosis of thyrotoxicosis and myxoedema the concentration of radioactive iodine might be measured in the gland itself, in plasma as the percentage of dose per litre, and in urine as the percentage of dose excreted. In the plasma the concentration was weak and therefore not easily measured. In the urine it could usefully be measured as the amount excreted over 48 hours or over different periods, such as 8–12 hours after the injection. In thyrotoxicosis the excretion curve fell rapidly and then flattened out, while the reverse was true in myxoedema. Broadly speaking, the less radioactive iodine in the urine specimen between 8 and 12 hours, the higher the basal metabolic rate.

Radioactive iodine might also be used in indicating the iodine content of histological material obtained from the thyroid gland. Contrary to what has been stated, there was no evidence that the pituitary concentrates iodine.

Anticoagulants

Professor H. W. FULLERTON (Aberdeen) then read a paper on anticoagulants. There was little doubt of the value of heparin in the prevention of arterial and venous thrombosis, but the expense of the drug and the necessity for giving it intravenously had confined its use to hospital. The clotting time should be kept at 30 minutes, and this was rarely attained by dosage less than 75–100 mg. every four hours. It was obtained by a continuous intravenous drip, and could therefore be used only for a few days. Dicoumarol, which can be given by mouth and which lowered the prothrombin concentration, was becoming more firmly established in the treatment of venous thrombosis and coronary infarction. The American Heart Association had recently compared the results of treating 386 patients with the latter disease by conventional methods with those of treating 432 patients with conventional therapy plus dicoumarol. Of the control group 24% died, whereas of the dicoumarol group only 14.9% died. Of the control group 25% had one or more thrombotic complications (secondary myocardial infarct; pulmonary, cerebral, or peripheral emboli; venous thrombosis), whereas only 12% of treated cases were so affected.

No uniform scheme of dosage can be applied, and each individual needed to be controlled by a regular estimation of the plasma prothrombin, otherwise there was great danger from haemorrhage. Plasma lipoid played an important part in coagulation which had not previously been recognized. While the venom-and-lecithin method was the most accurate for prothrombin estimation, the venom alone gave a more accurate method of estimating coagulability, which was much influenced by the amount of fat in the diet. In dicoumarol therapy, while the prothrombin in the blood was lowered the lipoid activator was increased. He therefore thought that the venom test was the best for controlling this therapy. He usually gave 350 mg. on the first day, 200 mg. on the next day, and then endeavoured to keep the accelerated clotting time by the venom test at 40 seconds. There were no definite rules about how this should be done; not only should the accelerating clotting time be noted but also the speed at which it was rising. When haemorrhage occurred it was frequently in the form of haematuria and was controlled by transfusion.

Professor A. P. THOMPSON (Birmingham) said that he had treated patients with heparin by intravenous drip with success, and he felt it was safer than dicoumarol. With this drug he had had two deaths: in one there was a suprarenal haemorrhage; many sub-pleural and sub-endothelial haemorrhages had been a feature at the necropsies.

Professor R. E. TUNBRIDGE (Leeds) recorded a case he had seen where a patient had died although the prothrombin time had been normal; the necropsy revealed many small endothelial haemorrhages and small haemorrhages in many organs.

Professor FULLERTON in reply agreed that heparin was much safer than dicoumarol, but it could not be given for the month or six weeks necessary for the treatment of coronary thrombosis.

SECTION OF PATHOLOGY AND BACTERIOLOGY

Chemotherapy in the Treatment of Malignant Disease

The discussion on chemotherapy in the treatment of malignant disease was introduced by Professor E. C. DODDS (London), who pointed out the obstacles to a rational approach to this problem, since the cause of the disease was still unknown. A great variety of chemotherapeutic agents had been tried, and the most hopeful of these fell into two main groups: (1) substances inhibiting the growth of tumours indirectly by their effect on the host background, and (2) substances with a directly toxic action on malignant cells.

In the first group stilboestrol was the outstanding example, and had been used in the treatment of carcinoma of the prostate with remarkably successful results, although claims for complete cure could not be substantiated. In the second group of cytotoxic agents, of which urethane and the nitrogen mustards were examples, the margin between the therapeutically effective and the toxic dose was small. These substances acted directly on cancer cells.

A new approach had been made with the use of anti-folic-acid compounds which, since folic acid was an essential requirement for neoplastic growth, suppressed selectively the growth of tumour and leukaemic cells. Encouraging results had been obtained with these compounds in the treatment of spontaneous and transplanted tumours in animals, but more work was needed to assess their clinical value.

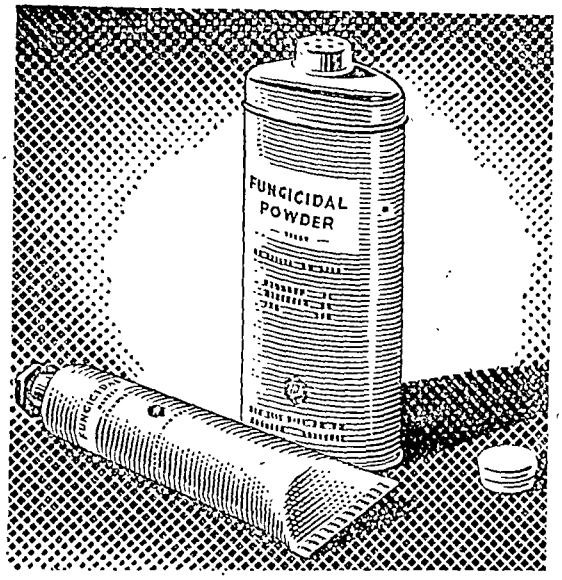
Professor A. HADDOW (London) restricted his remarks to one type of substance of chemotherapeutic interest with a direct action on the tumour cell. This was a new series of some 200 compounds, mainly aromatic nitrogen mustards or analogous substances. He was representing a team of workers that included G. A. R. Kon, W. C. J. Ross, P. C. Koller, A. Loveless

ANAESTHETICS

'TRILENE'—in addition to its use in analgesia—is employed with success for the production of a light plane of anaesthesia. Contra-indications are few, and recovery is rapid with no unpleasant after-effects.

Containers of 250 *and* 500 *c.c. Crushable ampoules of* 1 *c.c. in boxes of* 5*; ampoules of* 6 *c.c., boxes of* 1, 5 *and* 25.

'KEMITHAL' SODIUM is a highly efficient ultra-short-acting barbiturate used for the production of basal hypnosis or full surgical anaesthesia of short or prolonged duration. Respiratory depression is minimal, and experience has shown that the occurrence of laryngeal spasm is less frequent than with similar agents.



Ampoules of 1 *or* 2 *grammes, with or without distilled water. Containers of* 5 *and* 25.

Other anaesthetics and analgesics include : 'Avlon' brand Chloroform, Procaine, and Pethidine (with and without Hyoscine).

Undecylenic Acid in the treatment of fungous infections of the skin

THE STUDY of possible fungicidal agents in sweat led to the use of naturally occurring fatty acids in therapeutics.

It has been found that undecylenic acid and its derivatives are among the most effective fungicidal agents, especially valuable in the prophylaxis and treatment of tinea pedis and other dermatophytoses.

Fungicidal Ointment-Boots contains 5% undecylenic acid and 20% zinc undecylenate in a vanishing cream base. Fungicidal Powder-Boots contains 2% undecylenic acid and 20% zinc undecylenate in a starch and kaolin base. They do not irritate the skin and may be used safely by patients for self-treatment over long periods.

Fungicidal Ointment-Boots

Tubes of approx. 1 oz.

Fungicidal Powder-Boots

Sprinkler containing approx. 2½ oz.

SUPPORT WITH COMFORT

Abdominal Ptosis in all its forms can be reliably treated by the Curtis Abdominal Support No. 1. It gives direct anterior-posterior pressure but has no undue constricting effect on the lower abdomen and assures complete freedom of hip movement; in other words, it gives gentle pressure and firm support *only* where it is needed. Lasting comfort in wear is assured at all times by the high standard of workmanship and finish. This is one of the many types of Curtis Products, whose use is recommended by the Medical Profession.

CURTIS R.T.M. MODEL No. 1 ABDOMINAL SUPPORT

H. E. CURTIS & SON, LTD.

4, MANDEVILLE PLACE, LONDON, W.1

Phone: Welbeck 2921. Grams: Curtis, Welbeck, 2921.

Sole Makers of Curtis Appliances, Abdominal Supports and Corsets, Elastic Hosiery, Trusses, Colostomy Appliances, etc.

E. S. Horning, and R. J. Goldacre. While it seemed not unreasonable to expect improved therapeutic efficiency from chemical modification of the aliphatic types so far employed, clinical trial of a few new types, especially the *bis*-chloroethyl derivative of β-naphthylamine, indicated that therapeutic effects were still largely confined to those tumour types—especially Hodgkin's disease—which were most responsive to the aliphatic chloroethylamines. The new aromatic substances had, however, some practical advantage in that they could be readily administered by mouth for considerable periods. Examples were shown of the clinical responses obtained, especially in Hodgkin's disease, chronic lymphatic leukaemia, and plasmocytoma.

That the action of such substances was largely a direct one on the cell was illustrated by cytological evidence—induction of nucleic-acid-deficient zones in the chromosome, chromosome breaks, defects of chromosome spiralization, anaphase bridges, and ejection of fragmented chromatin into the cytoplasm in the form of micronuclei. The significant effect was believed to be produced in the resting stage, with consequent damage to the mechanism of mitosis which became evident cytologically only in the course of cell division; such damage tended to augment in successive divisions until the cell was no longer viable.

Both the clinical responses and cytological effects induced by these substances clearly illustrated their radiomimetric character, and this was further seen in the damage which they inflicted upon cell division in the bone marrow and testis, and in the characteristic and permanent bleaching of pigmented hair in the areas overlying the site of subcutaneous injection: the last effect was quite indistinguishable from a similar effect produced by irradiation with *x* rays or the subcutaneous injection of plutonium.

Since *x* rays and other agents with similar growth-inhibitory properties were known to be carcinogenic, it became important to decide whether the new aromatic mustards were endowed with the same property. Extensive biological tests had now shown this to be so. Examples were shown of sarcomata induced at the site of subcutaneous injection, and there was evidence that these substances were also active by mouth and so might induce carcinomata in the intestinal tract. Many of the induced sarcomata were of exceptional interest on account of their high incidence of cytological abnormality, a feature which appeared to be characteristic and was maintained on transplantation over many generations. Professor Haddow went on to discuss the mode of action of these new chemically active substances on the cell and looked forward to the eventual prospect of correlating the chemical properties of a carcinogen with the chemical and genetic properties of particular chromosome regions. He concluded that the frontal attack on the chemotherapy of cancer was not likely to be the most successful, since workers were inevitably drawn back to questions of the mechanism of carcinogenesis, questions which were more fundamental and hence more fruitful in the long run.

Professor F. DICKENS (London) discussed the use of folic acid antagonists in experimental cancer therapy. Folic acid as a member of the B group of vitamins was essential for cell growth, being particularly concerned with haemopoiesis and probably with the synthesis of nucleic acids and related compounds. Actively growing cells, such as bone marrow and intestinal mucosa, had a special need for folic acid, which was also the vitamin present at the highest relative level in neoplasms. It therefore seemed logical to attempt the suppression of tumour growth by anti-folic-acid compounds such as aminopterin and anethopterin.

Professor Dickens and his colleagues had tested the effect of both folic acid derivatives and anti-folic acid substances in the treatment of mammary adenocarcinoma in mice. With the former group they failed to obtain inhibition or regression of tumour growth, but with anethopterin, given daily by intraperitoneal injections, only two of six mice tumours grew in the same way as in the control animals. Two tumours which had regressed started to grow again and two regressed completely. The treated animals showed pronounced leucopenia and haemoconcentration associated with diarrhoea. Larger groups of mice were now under test.

Sir STANFORD CADE (London) described his experience with both cytotoxic substances and hormones in the treatment of clinical cases. The nitrogen mustards had produced striking improvement in Hodgkin's disease and other reticuloses, and were particularly valuable in cases which had become resistant to *x* rays, but patients who relapsed usually failed to respond to a second course. Urethane was useful in chronic leukaemia, and had the advantage that the maintenance dose could be continued for years. Aminopterin, the anti-folic-acid compound, had been given in acute and chronic leukaemias (lymphatic, myelogenous and monocytic). It acted on both normal and abnormal blood cells and could reduce the total leucocyte count to very small numbers remarkably quickly, but the effect was only temporary.

Discussing the use of hormones, Sir Stanford Cade said that about 10% of prostatic cancers failed to respond to stilboestrol; a very large dosage had no advantages. He had employed both oestrogens and androgens in the treatment of mammary cancer; only oestrogens were effective in male mammary cancer, and in women they should not be given until ten or more years after the menopause. Testosterone was particularly effective against metastases in bone in female mammary cancer; by controlling tumour growth and allowing bone replacement it gave marked relief of symptoms. The tendency to masculinization was not related to dosage. There were no significant blood changes, although hypercalcaemia had been reported and there was an excessive excretion of 17-ketosteroids during treatment.

In the general discussion which followed, Professor R. J. V. PULVERTAFT, the president of the Section, pointed out the analogy between the events of carcinogenesis as described by Professor Haddow and the induction of adaptive modifications in bacteria. Professor HADDOW agreed, and stated that in fact many of the induced tumours had proved on test to be quite insensitive to the cytotoxic action of the compounds used to induce them.

SECTIONS OF SURGERY AND NEUROLOGY AND PSYCHIATRY

Thursday, June 30

Head Injury

With Mr. T. V. PEARCE (Harrogate) and Mr. W. R. HENDERSON (Leeds) presiding, Mr. G. F. ROWBOTHAM (Newcastle) opened a discussion, in the absence of Professor Norman Dott owing to illness, on the treatment, after-treatment, and sequelae of closed injuries to the head. Speaking of the diagnosis and management of the acute stage, he said that head injuries might provide difficult problems in diagnosis. Distortion of the brain was the essential lesion, and the whole brain was involved. Associated injuries must not be overlooked, and they might complicate the clinical picture; injuries to the cervical vertebrae were specially important. He distinguished between the intrinsic injury to the brain (contusion, laceration, diffuse neuronal injury) and the many complications which might develop. The intrinsic lesion might be overwhelming and cause death, but more attention to, and study of, the extrinsic complications should lead to lives being saved.

Careful supervision and nursing were required in the acute stage. Attention to feeding, bowels, bladder, skin, mouth, and eyes were specially important, while restlessness required treatment. It was difficult to know how often secondary complications occurred, or to visualize what was going on within the skull. Nevertheless, if they could control the complications they would save many lives. From studying post-mortem material he believed that even a thin layer of extra-dural blood could turn the scales and cause death. If consciousness was returning, operative interference was rarely required. Dehydration played no part in treatment. When there was grave doubt about the advisability of operation he advocated an exploratory trephine or "inspection hole" so that the site of possible intracranial haemorrhage could be looked at. He stressed the dangers of inadequate debridement of scalp wounds; this might lead to serious intracranial complications.

Dr. W. RITCHIE RUSSELL (Oxford) emphasized the difficulty at necropsy of knowing whether the visible abnormalities were in fact the cause of death. Most cases of head injury did well on "sheer neglect," but perhaps 20% required help with

rehabilitation. He advocated: (1) During the acute stage an environment of confident optimism, which prevented needless anxiety; (2) graduated physical exercises started early and pursued vigorously; (3) some form of advice service to which those patients could turn during convalescence.

A rehabilitation programme for the patient to attempt was helpful, and some competent person should be available to discuss matters fully with him. An early return to a few hours' work a day was specially valuable, but dangerous occupations might have to be given up for a time. Insistence on light work was often undesirable. Half a day spent at hard manual work might be much less tiring than a whole day at "light" work. An essential principle of rehabilitation was that the patient should practise those movements or activities which caused symptoms. For example, orthoptic exercises might be very helpful when reading led to blurring of vision or headache. Where disability was gross or the occupation specially dangerous the situation should be faced without delay, and if necessary a change of occupation advised. The head-injury advice bureau at Oxford had been valuable. Developments along those lines would be a useful form of preventive medicine.

Dr. E. STENGEL (London), speaking of the psychiatric aspects of head injury, said there was no phase following head injury in which the handling of the patient should not be guided by the psychiatric approach. The psychiatric approach was an attitude of mind which made one see an illness or accident as something that happened to a personality rather than to a part of the body. It also implied a distrust of uninformed common sense. They were less concerned than were their predecessors with separating the so-called functional from the organic features among the symptoms following head injuries, and aimed at stimulating the resources of the undamaged parts of the brain by rehabilitation and psychotherapy. Head injury was felt to be a psychic trauma much more than injury to almost any other part of the body. The head was the most significant part of the body image. Neurotic symptoms were apt to emerge when the ability of the personality to deal with the impact of emotional stress had suffered as the result of structural damage. He fully supported Dr. Ritchie Russell's proposal for the establishment of advice bureaux for those with head injuries, and thought that a psychiatrist versed in the problems concerned might be an asset on the staff of such a centre; he would also study the problem of accident proneness, which was part of a specific character structure.

In the discussion which followed, Mr. T. V. PEARCE said that he was surprised to find that the industrial insurance companies were not much impressed by the alleged difficulties in dealing with head injury cases. Dr. D. ENGEL described an increased permeability of the blood–brain barrier in the acute stage. Dr. HUGH GARLAND advocated care in what is said to the patient about fractures of the skull. Dr. GORDON CAMPBELL (San Francisco) referred to associated cervical lesions causing headache and even giddiness. Dr. J. G. GREENFIELD said that pontine lesions were rare, but the clinical picture in fatal cases often indicated a hypothalamic cause of death.

SECTION OF ANAESTHETICS

Thursday, June 30

Dental Anaesthesia

With Dr. H. B WILSON (Aberdeen) in the chair, the discussion on dental anaesthesia was opened by Dr. W. S. MCCONNELL (London), who said that traditionally nitrous oxide was regarded as the safest and least harmful of anaesthetics. It was therefore administered regardless of its limitations, often with poor results. Its "safety" depended on the anaesthetic being abandoned at the whim of the anaesthetist and perhaps before completion of the operation. A physiological insult was offered to a patient by using a gas whose anaesthetic potency was so low that oxygen deprivation had to be used to augment its effect. He stressed the risks of so subduing a struggling patient. Nitrous oxide was contraindicated in children, who had a large oxygen demand and small vital capacity; in large muscular men—the "ageing athlete," who might be resistant when there was any psychological intolerance of general anaesthesia; and in patients who had a pre-existing lesion, such as respiratory obstruction, lung disease, myocardial disease, or anaemia, which made anoxia dangerous. The speaker always made a point of using a strap around the patient's pelvis.

A film was then shown of the technique of continuous nasal nitrous oxide, illustrating the difficulties and their management.

Dr. STEPHEN COFFIN (London) discussed the problem of anaesthetizing children for dental extractions in the chair. They were difficult patients because of a raised metabolic rate, nervousness, and the accentuation of mechanical difficulties by a small mouth. It was important that a child's first anaesthetic should not affect adversely his reaction to future ones. Dr. Coffin preferred nasal nitrous oxide and oxygen, because, though less easy than other methods, it allowed adequate working time and had the advantages of a pleasant induction and a rapid and uneventful recovery. Premedication was not given routinely except in the younger and more nervous patients. Troubles that might occur during maintenance were: difficulty in balancing good anaesthesia and colour, rapid cyanosis in response to oxygen limitation, and mechanical difficulties which reduced the airway. He stressed the prime necessity for a human and friendly approach to dental anaesthesia in children.

Mr. BALENDRA (Ceylon), speaking as a dental surgeon, pleaded for team work so that clumsiness on the part of the dental surgeon might not upset the anaesthesia. He had devised a strap which was part of an apron and was therefore not so objectionable to the patient. He also felt it was unwise to operate on patients who had trismus. In these patients cardiac or respiratory distress appeared suddenly on opening the mouth; they should be anaesthetized lying down.

Dr. A. H. GALLEY (London) drew attention to the value of trilene for children. He used it in the Oxford vinesthene inhaler. Dr. E. F. ADAMS (Birmingham) appealed for the modification of dental apparatus so that the gas mixture could be varied by means of a foot control.

Dr. J. MCAULEY (Blackpool) found a small dose of curare more helpful in the obstreperous patient than thiopentone. Curare with cyclopropane was best for elderly patients with cardiovascular disease. Drs. G. CATHERINE EVANS (Herne Bay), G. S. W. ORGANE (London), and R. P. HARBORD (Leeds) gave examples of their own methods, and described in particular how they gained the confidence of children about to undergo dental anaesthesia.

Continuous Caudal and Peridural Analgesia

With Dr. G. S. W. ORGANE (London) in the chair, Dr. ROBERT A. HINGSON (Baltimore) outlined the history of caudal and peridural analgesia from Sicard and Cathelin in 1901 to the present day, referring in particular to the work of Lundy and Cleland. He showed the instruments he used for continuous caudal analgesia, pointing out that the sacral hiatus was easy to enter and that there were no structures other than the last sacral and coccygeal nerves which were liable to injury. The latter in any case could be cut with impunity so far as the anal sphincter was concerned. A common technical error was injecting fluid or air outside the sacrum and traumatizing the periosteum of the sacral canal, with the production of pain. No standardization of dose was possible—each must be "tailor-made" to fit the individual patient. He had used continuous caudal block to remove the sympathetic vascular tone from the lower half of the body, producing a "bloodless phlebotomy" for those conditions in which a classical phlebotomy might have been undertaken. Pulmonary oedema and eclampsia were examples of conditions in which phlebotomy had been used to treat a vasomotor crisis, and for which caudal analgesia was equally successful.

Dr. Hingson then described the use of this method in the treatment of eclampsia and showed how the sympathetic block relieved hypertension, thus reducing the work of the heart and relieving oedema. Oxygen therapy must always be used concurrently. He demonstrated Tuohy's needle, which allowed a fine catheter to be inserted into the peridural or subarachnoid space in either a cephalic or caudal direction at the wish of

the administrator. Other successful uses of the method had been in cases of chronic ulceration of the legs, thrombophlebitis, and acute arterial thrombosis. In all these cases every safeguard, and particularly oxygen, was needed.

Dr. WINIFRED PITKIN (New York), the British-born widow of the late Dr. George Pitkin, reviewed the neuro-anatomy of the parts concerned in continuous caudal block.

Caudal Analgesia in Obstetrics

Later, at a joint meeting of the Sections of Anaesthetics and Obstetrics and Gynaecology, Dr. ROBERT A. HINGSON read a paper on continuous caudal analgesia in obstetrics. He first referred to ancillary factors which helped to make women in labour more comfortable, such as air-conditioning, artistic wall decorations, music, and television. The safeguards without which he considered caudal analgesia should not be undertaken were a continuous drip infusion and oxygen therapy.

The method was not without its disadvantages from the obstetric point of view, 40% of multiparae and 80% of primiparae needing forceps delivery. The obstetrician must be prepared for this or else he should reserve caudal analgesia for those cases where forceps were going to be applied in any case. He had now managed many thousands of cases with only two maternal deaths, one due to a massive spinal injection and the other to infection following penetration of the rectum. A total of 600,000 cases had now been reported. The extent of the anaesthesia had varied from the xiphoid cartilage to the toes, the duration from one hour to weeks. He advised that hospitals should arrange for teams of workers to cover the whole 24 hours, each team consisting of trained nurses and doctors who would look after the patient continuously. Many statistical and other charts were then shown illustrating how the method had reduced infant mortality, particularly among premature babies. Dr. Hingson again warned his listeners against the use of this method by untrained people and in unsuitable surroundings.

Dr. A. H. GALLEY (London), in opening the discussion, reviewed the anatomical pathways for both sensory and motor impulses connected with labour. He felt that continuous caudal analgesia was contraindicated in cases of placenta praevia, because the relaxed cervix ceased to give support to the placenta. The main indications were: multiparae, breech presentations, continuous contractions of the uterus with much pain, rigid cervix, foetal distress, prematurity, and where forceps delivery was anticipated. Professor R. R. MACINTOSH (Oxford) inquired how Dr. Hingson sterilized his catheters.

In reply Dr. HINGSON again referred to the possible dangers of the methods, saying that it could "assassinate women" if in improper hands or unsuitable circumstances. His catheters were all autoclaved. Formerly he used shellac-coated catheters, but had now found a new plastic material, "vinethyl," and which could be autoclaved. Another type of plastic catheter (polythene) would not stand up to heat but had to be sterilized in aqueous antiseptic. Continuous caudal analgesia carried with it an inherent mortality of about one in 20,000 women, because in one in 10,000 cases a peridural infection followed, and this condition carried with it a 50% mortality.

SECTION OF OCCUPATIONAL HEALTH

Thursday, June 30

Tuberculosis and Occupation

The chair was taken in turn by the vice-presidents, Dr. W. BLOOD (London), Professor G. P. CROWDEN (London), and Dr. F. S. COOKSEY (London). Dr. ALICE STEWART (Harrow-on-the-Hill) opened the discussion by describing an investigation into the incidence of pulmonary tuberculosis in the boot and shoe industry in Northamptonshire. It had been known for at least fifty years that the shoe trade carried a high mortality rate from phthisis. Investigation, based on the results of a mass radiography survey, on notified cases, and on the medical records of men called up, showed that this was partly due to selective recruitment. The shoe trade employed more men with quiescent tuberculosis than other trades. The physique of men was slightly subnormal, and there was a strong family tradition, so that workers were often interrelated. There was no evidence of a specific industrial hazard in boot and shoe factories, and the death rate for other diseases was below average.

The incidence of active tuberculosis was not uniformly distributed. Men and women employed in factories with large workshops contracted the disease more often than those in factories with small workrooms. The phthisis rate per 1,000 was 2.9 in rooms with fewer than 20 workers and 10.4 in those with over 80 workers per room. This same relationship between size of workroom and incidence had been found in the clothing industry. Further work would be necessary before it could be stated categorically that spread of infection was a fundamental cause of this high rate, but it might be an important factor in the epidemiology of other diseases.

Dr. W. POINTON DICK (Denham), discussing the advantages of mass radiography surveys in industry, said that 25% of those over 15 years old worked in factories. With the recent proposal that each worker should bring along a non-factory worker it would be possible to survey a substantial proportion of the adult population. Between 75 and 85% of the total population volunteered, and the degree of response was usually high where relations between management and workers were good. In return visits it was found that the rate of new cases per 100 examined was reduced by a third.

Dr. F. R. G. HEAF (London) said there were three important factors in the resettlement and rehabilitation of the tuberculous. First, it was never certain that a tuberculous person had recovered from his disability. Although there were few reliable figures in the follow-up of tuberculous cases, there was sufficient evidence to demonstrate a high relapse rate. Important factors in preventing relapse were high standards of housing and nutrition and routine medical examination at least once a year. The night sanatorium which offered care, nourishment, and rest had great possibilities in the future.

Secondly, it was not possible to assess the capacity for work of tuberculous persons except by trial and error. Certain occupations such as outdoor work, which was usually heavy, and high-pressure team-work were undesirable. Where possible the tuberculous should be specially trained so that their work had an economic value.

Thirdly, when the disease was active it was usually infectious, but it was probable that inherent resistance was the most important factor in infectivity, and that exogenous infection apart from the primary infection played a small part in causing active disease in those already infected. Financial assistance played a vital part in rehabilitation. This could sometimes be assured by contributions from certain authorities, but to apply a means test would do great harm.

Dr. E. H. CLUVER (S. Africa) said that in his country they were working on the assumption that the primary infection must be avoided. There would be extensive tuberculin testing of the African population from which gold-mining labourers were recruited. Those with a negative reaction would be given B.C.G. vaccine.

Dr. PETER EDWARDS (Market Drayton) said that many of the "incurables" could work and should be given a chance. Untutored idleness was bad for the tuberculous. Exogenous infection was an important factor in spread of the disease but could be controlled by proper sanatorium treatment. It was vitally important to educate the positive case, but a hard core of 10% were ineducable. At Papworth the value of education and sanatorium control was proved by the numbers of children and adults who had never become infected. Dr. BRIAN DAVEY (Oxford) made a plea for using mass radiography as an instrument for epidemiological research.

In reply Dr. HEAF said that tuberculin tests showed that a much higher percentage of the population in the lower age groups was escaping primary infection. B.C.G. vaccination could probably prevent the primary lesion from becoming dangerous. Later, infection by the exogenous route certainly took place, but it need not be harmful if the inherent resistance of the infected was high. Dr. ALICE STEWART suggested that it was easier to stop infection than to attempt to raise the resistance of the total population.

SECTION OF RHEUMATOLOGY

Thursday, June 30

International Congress at New York

Dr. G. D. KERSLEY (Bath) gave his impressions of the seventh International Congress on Rheumatic Diseases held in New York. Naturally, he said, discussions and clinical sessions tended to centre on endocrinology, so much so that Dr. Philip S. Hench coined the word "rheumocrinology" for this field. Much interest was also shown in the histology and microchemistry of connective tissue and their application to the "collagen diseases." Under this heading Professor Walter Bauer discussed rheumatic fever, rheumatoid disease, spondylitis, generalized lupus erythematosus, dermatomyositis, scleroderma, and polyarteritis nodosa.

These diseases had much in common, including a favourable reaction to "cortisone" (compound E), but Bauer advised that these syndromes should be kept separate until more was known of their specific aetiology. The widespread microdermal changes in rheumatoid disease were considered a non-specific response to some biochemical reaction, though they occurred much more frequently in this condition than in any other. Steiner (Detroit) alone maintained that the absence of reticulin network and the compactness of the focal lesions in rheumatoid disease allowed him to differentiate with certainty these lesions from those more rarely seen in other conditions.

The old difference of opinion about the interrelationship of ankylosing spondylitis and rheumatoid arthritis was maintained, the Americans considering the two conditions identical in spite of the different age and sex incidence, rarity of nodules and biopsy changes in the muscles in spondylitis, and their different reactions to gold and *x*-ray therapy.

In the field of orthopaedic surgery the outstanding pre- and post-operative care of cases undergoing cup arthroplasty for arthritis of the hip at Smith-Petersen's clinic at Boston was remarkable, the surgeon himself supervising all exercises during the early stages and rehabilitation being carried on for as long as two years. This operation was still being performed for spondylitic cases, but a second conservative operation was often indicated some eighteen months later. No walking was permitted without crutches for at least six months.

Excision of the heads of the metatarsals where there was pain and deformity was giving good results, and similar excisions of the acromial process, the head of the radius, and the lower end of the ulna were being carried out quite frequently when indicated.

A number of papers were read on the use of endocrines in rheumatic disease, notably by Hench and Kendall (Mayo Clinic), Thorne (Boston), and Woolfson (Chicago). Later a series of cases so treated were seen and examined. In addition to the Mayo Clinic, five other centres were given sufficient cortisone to treat two cases each for two weeks. Each centre confirmed the results obtained at the Mayo Clinic. The use of these hormones could not yet be looked upon as a new treatment likely to be available soon. Not only were supplies so limited that only research centres were likely to have any for some time, but the present cost of about £4,000 for two weeks' treatment was prohibitive. Much more needed to be learnt about actions and side-reactions.

"ACTH" (Armour), the corticotropic hormone of the anterior pituitary, and cortisone (Merck) (compound E acetate), 17-hydroxy-11-dehydrocorticosterone, a steroid from the adrenal cortex, had very similar properties, the former stimulating the adrenals to produce the latter. The dosage required, however, was so great that the contamination of ACTH with "pitressin" would often cause a rise in blood pressure, faintness, and vomiting.

Cortisone given intramuscularly in a dosage of 100 mg. a day produced a dramatic temporary remission in all the collagen diseases and also in gout, and was believed to be of benefit in treating such diverse conditions as metastatic carcinomatosis, hyperpiesis, and the shock of coronary thrombosis. Its action therefore was obviously a fundamental one, possibly on connective tissue, and not specific to rheumatic disease.

In rheumatoid arthritis some symptomatic improvement—relaxation in tension and easing of pain—began within a matter of hours. Within a week, pain largely disappeared, swelling was reduced, the appetite improved, weight was gained, anaemia was corrected, and the sedimentation rate began to drop. However, twenty-four hours after the cessation of treatment some falling off in the improvement was noticed, and often within a week the patient had relapsed, perhaps 80% of the improvement being lost. In rheumatic fever a similar result was obtained, but in only one case did a relapse occur immediately treatment was stopped.

Relief was experienced in attacks of gout within one to four hours, but about four days after the withdrawal of ACTH or cortisone, unless colchicine was administered in large doses, an acute attack occurred owing to the temporary production of a negative phase of corticosteroid production. This artificially produced attack was associated with all the usual chemical and clinical phenomena of gout and of 11-oxysteroid depression. This suggested that gouty individuals had a poor "stress" response from their anterior pituitary glands to shock, trauma, infection, or strain, and that this was the mechanism by which the trigger factors in gout acted.

Woolfson postulated that this sluggish corticosteroid response, together with an abnormal androgen, which was not a precursor of 17-ketosteroids and which helped to regulate a hereditary hyperuricaemia, explained the age, sex incidence, phases of gout, and the abnormally low 17-ketosteroid excretion in this disease. The latter was not due to difficulty in excretion, as testosterone administered to the gouty patient immediately produced a normal ketosteroid response.

In conclusion Dr. Kersley said it was impossible at the moment to define the significance of the recent discoveries in relation to the anterior pituitary and adrenal cortical hormones of the "carbohydrate" group or even their site of action. Their action must be fundamental rather than specific for rheumatic disease, though they affected beneficially all the collagen diseases and probably helped to explain the way in which the same triggers of shock, fatigue, infection, etc., adversely affected all these diseases. To produce results large doses had to be used, and this treatment could not be looked upon as simple replacement therapy, like insulin in diabetes or thyroid extract in myxoedema. He pointed to the absence of arthritis in Addison's disease. In certain diseases it might be that large doses of these steroids might act biochemically, as in the use of massive doses of vitamin C with arsenic, or the compounds may be catabolized over-rapidly in certain people. The only thing that was clear was that a new and wide field for research had been opened up with a reasonable hope of securing a valuable therapeutic weapon at some time in the future.

SECTION OF MEDICINE

Friday, July 1

Cirrhosis of the Liver

Professor R. E. TUNBRIDGE (Leeds), the president, took the chair, and Dr. N. H. MARTIN (London) opened a discussion on cirrhosis of the liver. He said that since Hanot described the condition 50 years ago the studies had been mainly of connective tissue, but what they really wanted to know was the condition of the liver cell. By means of liver biopsy it was possible to follow the changes from the acute phase to the stage of restoration as well as the chronic progressive disease, and it might thus be possible to discover how many recovered and how many subsequently broke down. However, it was only a small sample, and one only of the right lower lobe of the liver. Experimental evidence during exercise showed that there was a markedly diminished flow through the liver; if exercise were allowed too early during the recovery from acute hepatitis, the cells might be intermittently deprived of oxygen and thus permanently damaged. This might also explain the tendency to relapse.

In yellow fever there was little autolysis of the liver cells, and therefore there was rarely any fibrosis; whereas when the liver was poisoned by carbon tetrachloride there was marked autolysis, which he regarded as precirrhotic. It had long been known that carbohydrate had a protective action on the liver; but recently choline and methionine had been shown to

protect the liver from fatty infiltration. If sulphur-containing amino-acids, such as cystine, were cut out of the diet, small areas of haemorrhage and necrosis developed, while α-tocopherol (vitamin E) protected the whole liver when there was a deficiency of cystine and methionine. It was therefore most important not to starve the patient but to ensure an adequate protein intake.

Liver-function tests were disappointing. He usually used four: (1) Circulating bilirubin; (2) total plasma protein, and albumin–globulin ratio; (3) thymol turbidity; and (4) alkaline phosphatase. Steady deterioration shown by these tests indicated obstructive jaundice, whereas they showed gradual improvement in cases of acute hepatitis. The thymol turbidity test continued positive long after the serum bilirubin, urinary bilirubin, and urobilinogen had returned to normal levels. This test might be of value in prognosis, and those cases in which it was positive over a long period might be ones that would subsequently develop cirrhosis. With regard to plasma proteins, estimation of the total protein did not help very much, since it was very variable, but gross inversion of the albumin–globulin ratio was of significance.

Dr. M. H. K. HAGGIE (London) said that everyone had been taught that alcohol caused cirrhosis. He had therefore studied the notes of patients with evident cirrhosis who had come to necropsy at the London Hospital over a period of 40 years to ascertain how many gave a history of alcoholism, and had found that there had been a falling incidence in recent years.

	Alcoholics Per cent.	Teetotal Per cent.	Not Recorded in Notes Per cent.
1907–16 ..	50	31	19
1917–26 ..	33·3	33·4	33·3
1927–36 ..	29·7	46	24·3
1937–46 ..	13·6	54·5	31·8

He had also examined 19 patients with cirrhosis who had been in the hospital in the past two years. They had consisted of 12 women and 7 men, whereas in the old literature the incidence was three males to one female. This also indicated a changing cause. Two of the 19—one a barman and one a barmaid—were alcoholics. He therefore thought that alcohol was a factor in the cause of cirrhosis; but alcoholics often did not eat, and were therefore deficient in the necessary protective factors.

Mr. J. E. RICHARDSON (London) said that surgery was mostly concerned with the complications of cirrhosis—namely, haematemesis and ascites. It had been suggested in the past that portal hypertension might increase the liability of the gastric mucosa to ulcer formation and that gastrectomy was the right treatment; but in his experience a ruptured oesophageal varix was always found at necropsy. Further, if the lower end of the oesophagus was studied radiologically after swallowing barium the indentations of oesophageal varices could always be found in patients who had had recurrent haemorrhages. While ascites was often mechanical, it was sometimes also biochemical, and therefore a gross disturbance of the albumin–globulin ratio was an indication against surgery.

The main cause of post-operative deaths was oozing of blood, and therefore fresh blood should be used for transfusion, since stored blood was deficient in prothrombin and those patients also had a low prothrombin concentration in the blood. Many operations had been considered. Sclerosing fluid had been injected through an oesophagoscope into the varices; but the thrombosis might spread dangerously after that procedure, and it did not remove the cause of the varices. Splenectomy was dangerous because of the large number of vascular adhesions which had to be divided. Recently shunt operations had come into favour, such as anastomosing the splenic vein to the left renal vein, or the portal to the inferior vena cava. Anastomosis of the superior mesenteric to the inferior vena cava and of the inferior mesenteric to the left spermatic had also been performed. The spleno-renal was the easiest technically; it was possible that the porto-caval might eventually prove the best, since it gave the biggest shunt. The results were naturally somewhat better in cases of extrahepatic obstruction than in those of cirrhosis, but the operation carried a mortality rate as low as 10% and had given survival rates of 3½ years up to the present time without recurrence of the bleeding. In cases of ascites it had given survival of 18 months to the present time with no subsequent tapping.

Dr. E. R. CULLINAN (London) said that when Laënnec described cirrhosis 130 years ago he had referred to the golden-yellow colour of the liver; the name had been subsequently attached to sclerosis. He did not believe that acute hepatitis frequently progressed to cirrhosis. He was writing to one in five of the troops who developed hepatitis in the Middle East in 1942 and had had a very good reply; few of them had had subsequent trouble. He thought that patients with this disease needed rest for a considerable time after recovery and that it was vital to feed them to get a quick recovery. Extra rations, including meat and skimmed milk, were now available.

There was a difference between multiple nodular hyperplasia with recurring attacks of jaundice due to necrosis and subacute necrosis, which finally ended with cholaemia and death in jaundice and coma. The state was usually associated with cirrhosis. The first group never developed ascites. The latter condition was a very prolonged one. Early stages were quiet and produced few symptoms apart from attacks of gastro-enteritis, but eventually there were portal hypertension, oesophageal varices, splenomegaly, and ascites. The patients practically never gave a history of preceding jaundice.

Alcohol was a predisposing cause of cirrhosis; it was therefore important to recognize the early stages, since by stopping the patient's drinking it might be possible to prevent the development of portal hypertension. Those patients also often had anorexia, and it was important to get them to eat a full diet, generous in protein and carbohydrate and not restrictive in fats. Such a diet would certainly contain enough methionine. Vitamin-B complex should be given. The evidence in favour of giving androgens was equivocal. Bleeding might be the first sign of the disease, and accounted for 4% of cases of haematemesis; patients rarely lived two years after such an incident. Surgery therefore played an important part in prolonging life in those cases. Patients with ascites sometimes did well with a low-salt diet and mercurial diuretics, but rarely survived three paracenteses, which had the effect of hastening the onset of cholaemia, with confusion, semi-coma, and finally death. Porto-caval shunt therefore did offer some hope of prolonging life.

Dr. H. STEINITZ (Tel-Aviv, Israel) thought that the laevulose-tolerance test was of value and that a test of carbohydrate function should be included. Though they saw many kinds of liver damage in his country—particularly as a consequence of amoebiasis and infective hepatitis—true cirrhosis of the liver with portal hypertension, haematosis, and ascites was very rare. He did not know the cause, but there was almost no drunkenness in Israel or in the Arab population of Palestine.

Dr. R. R. BOMFORD (London) said that the theory that acute hepatitis led to portal cirrhosis was an attractive one but was without foundation. He asked whether every patient who had a palpable liver as his only abnormality should be regarded as an early case of cirrhosis. Dr. J. R. FORBES (Wrexham) said that one knew many people addicted to alcohol who never appeared to develop cirrhosis, and wondered whether there was a constitutional factor. Professor A. P. THOMSON (Birmingham) said that alcohol played a contributory part in the causation of cirrhosis. The poor in the past had had a diet deficient in lipotropic factors which would protect the liver after the drinking of alcohol. In cases of diabetes fatty infiltration and palpable liver were common, but cirrhosis was rare. He had known patients have recurrent haematemesis for 20 years.

Salicylates in Rheumatic Fever

Dr. G. WATKINSON (Leeds) then read a paper on salicylate therapy in acute rheumatic fever. It had first been advocated 73 years ago, but apart from its analgesic and antipyretic actions there was no agreement on its value. A new phase of therapy began in 1943 with the publication by Coburn of the dramatic effects resulting from massive controlled therapy. He had attempted to assess the value of the therapy by treating 90 R.A.F. recruits (87 men and 3 women) aged 18 who developed rheumatic fever between April, 1947, and September,

1949, with salicylates in various doses. Of these, 21 had had rheumatic fever previously; 71 had had an upper respiratory infection in the preceding two weeks, mostly with a positive haemolytic streptococcal throat swab. The results in those observed for 18 months were as follows:

Station	No. of Cases	Previous Rheumatic Fever	Dosage of Salicylates gr./daily	Days before Afebrile	Days before Free of Pain	Average B.S.R. on Admission	Days before Normal	Relapses
1	25	4	14 mil. 11 less than 100	19·6	22·6	43·8	65·9	6
2	30	6	200	5·0	6·0	45·3	38·5	2
3	31	9	200–600	2·4	2·2	60·3	18·3	9

High dosage shortened the period of fever and pain and brought the sedimentation rate (Westergren) more rapidly back to normal. There was some objection to using the sedimentation rate as an index of activity of the disease, since some workers had suggested that salicylates would lower this in other conditions such as pulmonary tuberculosis. He had made some observations on this and had found that the salicylates did have some effect in other conditions but not in the same way as in rheumatic fever.

The six patients in the series who had had pericarditis responded well on doses that were adequate to keep the blood salicylate level above 40 mg. per 100 ml.

The effect on permanent valvular damage was perhaps the most important matter to determine. In that series the number of patients who had ended with valvular disease of the heart was not statistically different in any of the three groups. There had been fewer, however, in the high-dose group who were left with a systolic murmur and had been classified as having potential heart disease. The figures of that experiment compared with those of Coburn were:

Coburn			Watkinson		
Dosage of Salicylate gr./daily	No. of Cases	Valvular Disease of Heart Per cent.	No. of Cases	Valvular Disease of Heart Per cent.	Potential Heart Disease Per cent.
Less than 100	63	31·9	25	8	25
100–200 ..			30	16·6	23·3
200–600 ..	38	Nil	31	9·7	6·5

It seemed probable that none of the patients in the present series had had valvular defects before the attack of rheumatic fever, since they had been recruits, had just been through a medical board, and had had their chests *x*-rayed.

Toxic effects could be divided into three groups. In the first the symptoms were common but important, and did to some extent indicate that an adequate blood level had been reached. They were tinnitus, nausea, sweating, and transient vomiting. The second group were uncommon but serious, and included vertigo, drowsiness, mental upsets, and haemorrhage. The third group were common and alarming, and consisted of severe vomiting and hyperventilation. The occurrence of symptoms of the last two groups called for a modification of dosage.

Functional Uterine Haemorrhage

With Miss GLADYS KAY (Harrogate), vice-president, in the chair, Mr. V. B. GREEN-ARMYTAGE (London) opened the discussion by reviewing the history of endometrial biopsy. It was well to remember that functional derangements of several types might result in abnormal bleeding. For instance, it might occur in the patient with a hyperplastic (oestrogenic) endometrium, or in one with an endometrium so atrophic that no material for section could be obtained. On the other hand it might be seen in patients who had either a progestational endometrium or even delayed shedding of the premenstrual membrane, a condition possibly due to some disturbance of the process of constriction of the spiral arteries of the endometrium. Bleeding in all these types was painless and perhaps most frequently seen in the young. Few would deny that the feminine glandular system could be deranged temporarily, and spontaneous cure might account for some of the apparent successes of hormone therapy.

What was the bleeding factor and how could it be controlled? He referred to cases where the psyche controlled metrorrhagia, just as it did amenorrhoea. When it did the individual rather than her organs of generation must become the object of therapy. The hypothalamus influenced the pituitary gland, and presumably it was not until the emotional tension was relieved that there was a return to normality. Functional bleeding, then, was a symptom rather than a disease.

He had consulted records of 384 cases of functional bleeding seen in private between 1930 and 1949. The following table showed the pathological findings in 326 patients between 12 and 45 years of age.

Slight enlargement of uterus	97	29·7%
Small cystic enlargement of one or both ovaries	23	7·05%
Endometrial (oestrogenic) hyperplasia ..	117	35·8%
Atrophic mucous membrane	30	9·2%
Mixed or irregular-patterned endometrium ..	13	3·9%
No abnormal histology	28	8·5%
Polypi, glands or adenomata	14	4·2%
Endometrial tuberculosis	2	0·92%
Malignancy of corpus uteri	1	0·30%
Malignancy of endocervix	1	0·30%

In the series of 384 cases there were 63 cases of puberty or young-adolescent haemorrhage, 15 of which had to be corrected. Eleven patients were classified as having emotional haemorrhage when all other causes had been excluded. In 182 there were various stigmata of endocrine disorder, such as obesity, slight enlargement of the thyroid, etc.

Discussing treatment, Mr. Green-Armytage stressed the importance of first excluding physical, organic, conceptional, and more obvious endocrinal causes of excessive bleeding. If the patient was young and unmarried the administration of thyroid extract, 0.5 gr. (32 mg.) daily, increasing by 0.5 gr. weekly for six weeks, and Lugol's iodine, 10–15 min. (0.6–0.9 ml.), was excellent, but contraindicated in the thin or nervous subject. At the same time iron, liver, yeast, and possibly sedatives were given, and attention was paid to any source of mischief in the teeth, tonsils, and general hygiene. Very often change of food and environment was beneficial. If after 4–6 weeks of that treatment there was no improvement the "Hamblen Plan" was carried out. Stilboestrol, 2 mg. t.d.s., was prescribed for 20 days; at the end of 10 of these days ethisterone or progesterone, 10 mg. t.d.s., was given in addition. That regime must be undertaken at the onset of persistent bleeding. Stilboestrol, 5 mg. q.q.h., for 24–36 hours might be needed as a haemostatic, but there was a danger of profuse haemorrhage following this, necessitating immediate curettage. Androgen treatment might be preferred but was expensive. He did not use radium or *x* rays in this connexion. If a patient was at or about the age of 40 and had failed to react to hormonal treatment or curettage, then vaginal hysterectomy was the ideal procedure.

Dr. P. M. F. BISHOP (London), giving the viewpoint of the endocrinologist, said it might become the orthodox teaching that uterine bleeding was more intimately related to the condition of the uterine vessels than to the histology of the uterine mucosa. He had found that stilboestrol, 5–15 mg. 4-hourly, would stop bleeding within 24 hours, though it might cause nausea or vomiting. The second problem was to prevent troublesome bleeding, metropathia, and menorrhagia. The object in the former was to forestall the bleeding episode and substitute for it an apparently normal period. This could be done by giving progesterone, preferably by injection, in four doses of 20 mg. on alternate days ("medical curettage"). A repetition of the course of progesterone 20 days after the onset of the previous medical curettage would again forestall the tendency to a metropathic flooding.

Menorrhagia was a different problem, and probably mainly due to a disturbance of the normal oestrogen–progesterone ratio in the premenstrual phase. Individual cases required

different treatments—for example, chorionic gonadotropins to stimulate progesterone secretion (daily doses of 1,000 i.u.); progesterone to ensure total shedding of the endometrium; and androgens to antagonize the ovarian hormones, to atrophy the endometrium, or to exert a vascular haemostatic effect. In from one-third to one-half of the cases of functional menorrhagia a course of 10–15 mg. of methyl testosterone daily by mouth would reduce the bleeding, and remission followed for a few months. And there were cases of masked hypothyroidism in which 2–3 gr. (0.13–0.2 g.) of thyroid extract daily produced spectacular results. Endocrine therapy could offer no cure for functional uterine bleeding; nevertheless it could have limited, and on occasions spectacular, results. Endocrine therapy should be logically conceived, properly planned, and abandoned if it had obviously failed after a reasonable trial.

Dr. T. N. MACGREGOR (Edinburgh) said that each case at the Gynaecological Endocrine Clinic of the Royal Infirmary, Edinburgh, was investigated as follows: (1) Detailed history taken; (2) height, weight, and diet recorded (when indicated, an anti-obesity regime was adopted); (3) general physical examination, including haemoglobin estimation; (4) pelvic or rectal examination and endometrial biopsy; (5) given menstrual calendar and temperature chart for recording rectal temperature. At first, treatment was directed towards improving the general state of health. Functional uterine haemorrhages at puberty not responding to general measures could be treated effectively by progesterone (ethisterone, 20 mg. by mouth t.d.s., would clear up haemorrhage in 3–5 days, although the bleeding might be aggravated at first). Severe bleeding requiring immediate control was best treated by ethinyl oestradiol, 0.05 mg. t.d.s. Initial control of bleeding, whether by oestrogen or progesterone, was followed by the administration of ethisterone, 20 mg. t.d.s., from the 14th to the 24th day of the cycle. This treatment was repeated for 3–4 months. Metropathia haemorrhagica was treated similarly, but metropathic bleeding after the age of 35 should be investigated by careful curettage to exclude malignant disease. Such cases did not respond to progesterone so well as the younger cases, and often hysterectomy was necessary. But some cases did respond to short-wave diathermy, the response indicating mild pelvic infection, especially following childbirth or abortion. Male-hormone therapy was dangerous.

Professor A. M. CLAYE (Leeds), the president, asked what was the appropriate time for doing a curettage, and stressed the importance of exploring the uterus in women of 35 and over. He wondered why Dr. MacGregor used the rectal method for recording temperature. Dr. A. BARKER (East Kent) questioned the advisability of vaginal hysterectomy when there was a great possibility of endometriosis being present. He wanted to know the indications for implantation therapy. Mr. G. G. LENNON (Oxford) asked Mr. Green-Armytage if he did a vaginal hysterectomy when the cervix did not come down to the introitus, for many cases of functional uterine bleeding were in multiparae; and were cystic ovaries removed vaginally also? Dr. J. LÖVSET (Norway) thought metropathia was evidence of a Mendelian dominant.

Professor T. N. A. JEFFCOATE (Liverpool) considered that thyroid therapy was excellent. He did not think metropathia was so common as had been indicated. Polypi in the uterine cavity were often missed at curettage, and for that reason hystero-salpingography was useful. The uterine cavity should be explored by incision of the uterus prior to abdominal hysterectomy. Mr. G. W. THEOBALD (Bradford) said that the theory of the influence of the hypothalamus was one he had advanced many years before. Dr. ERWIN RABA (Israel) also contributed to the discussion.

In reply Mr. V. B. GREEN-ARMYTAGE said he regarded 12 days of bleeding (or inability to work) as indications for curettage. He removed the uterus vaginally even when the cervix did not descend, and he pricked or removed cysts of the ovaries vaginally.

Dr. BISHOP pointed out that even small doses of androgen could be harmful. The dosage must be kept under 300 mg. per month—for only two months at a time, with two-monthly intervals. If harmful effects were seen, they disappeared when administration was stopped, except for the deeper tone of voice. Implantation therapy was seldom indicated—ethisterone was not absorbed when implanted—and progesterone had to be put in deeply to avoid extrusion. There was no need to take the temperature per rectum. He endorsed the hypothalamic theory. Dr. MACGREGOR emphasized that, if endometrial biopsy was to be done, pregnancy had to be excluded. The only indication for implantation treatment was recurrent abortion, when progesterone was used. There might be a psychological effect of rectal temperature recording. Irregular bleeding in a woman older than 40 must be regarded as due to malignant growth until cancer was excluded.

SECTION OF PATHOLOGY AND BACTERIOLOGY

Friday, July 1

Pathology of Hypersensitivity Reactions

Dr. J. G. GREENFIELD (London), the vice-president, took the chair. Professor HILDING BERGSTRAND (Stockholm), discussing the pathological anatomy of hypersensitivity in man, thought the general term "hypersensitivity" was preferable to "allergy" if they were to appreciate the different manifestations in that group of disorders. They included anaphylactic shock—a rare disease in man—characterized by contraction of smooth muscle and dilatation of capillaries and small blood vessels due to an interaction between antigen and antibody in the tissues of the sensitized animal. A mild form of anaphylaxis, now becoming rare, was serum sickness, with joint pains and swellings, skin rashes, oedema, etc., appearing 7–10 days after injection of a foreign protein. The Arthus phenomenon was a severe local anaphylactic reaction of haemorrhage and ulceration following repeated intracutaneous injection of an antigen. Atopy was the American name given to a variety of allergic diseases in man, of which the prototype was pollen hypersensitivity; in asthma, contraction of the smooth bronchial muscle was a prominent feature, as it was in anaphylaxis. The skin rash of serum sickness had its corresponding atopic skin disease, such as infantile eczema. There was a group of hypersensitivity reactions associated with drugs which were not themselves antigenic but became so after conjugation with a protein. The tissue reaction here could be of either the atopic or the bacterial type; the latter was exemplified by contact dermatitis, in which there was a delayed, not an immediate, response to the antigen. In the bacterial type of tissue hypersensitivity, of which the tuberculin reaction was the prototype, all the cells of the body seemed to be sensitized, in contrast to the localized sensitivity of smooth muscle and endothelium in the anaphylactic reaction. That difference could be demonstrated by experiments on the avascular cornea.

Capillary damage was the main feature of the tissue changes in hypersensitivity diseases. Characteristically it occurred as a focal neurosis with fibrinoid thrombi and some secondary haemorrhage, and that capillary damage could probably explain such phenomena as urticaria, angioneurotic oedema, and joint swellings. Changes in the larger vessels had the character of periarteritis nodosa, with focal necrosis, intramural and perivascular cell infiltration, and proliferation of the vascular endothelium to such an extent that the lumen might be occluded. The secondary changes in the connective tissue consisted of oedema and focal splitting of the collagen fibres into reticulin fibrils which stained black with silver. That was followed by fibroblastic reaction and formation of the "rheumatic" granuloma. An outstanding feature of most hypersensitivity reactions was the localization in different organs, with a markedly focal distribution in the affected organ. That the localization was related to the nature of the antigen was suggested by the finding that rabbits sensitized with albumin developed vascular lesions of the periarteritis-nodosa type, whereas with gamma-globulin glomerulonephritis was the most prominent lesion. The capricious distribution of the lesions would account for the diversity of the hypersensitivity diseases—polyarthritis, endocarditis, pneumonitis, glomerulonephritis, periarteritis nodosa, lupus erythematosus, etc. He hoped that

there might be a closer integration of the clinical, serological, and pathological findings in these hypersensitivity disorders.

Professor M. J. STEWART (Leeds) demonstrated the histological changes in two cases of "allergic prostatitis," both in elderly asthmatics. The characteristic focal granulomata were present, together with a gross eosinophilia, present also in the glandular tissue, so that the eosinophils would presumably have been found in the urinary deposit. Professor K. R. HILL (Jamaica), who had recently worked with Professor Rich, thought that anaphylactic and bacterial sensitivity should be regarded as essentially similar; he discussed "collagenosis" and a paramyeloid condition, both of which were probably hypersensitivity tissue reactions. Professor R. J. V. PULVERTAFT wondered if the acute blood changes—haemolytic anaemia and granulocytopenia—following sulphonamide therapy were sensitivity phenomena; he was interested in the local eosinophilia that sometimes accompanied acute gastric ulcers and appendicitis. Dr. H. ROYLE (London) remarked on the importance of histamine in allergic reactions, but noted that eosinophilia was absent when histamine was used to produce these reactions experimentally. Dr. PURDON MARTIN (London) asked about auto-sensitization, with particular reference to encephalopathies.

Temporal Arteritis

Dr. C. V. HARRISON (London) said that temporal arteritis produced, in the elderly of either sex, a general illness which preceded and outlasted the local signs and which was much more severe than would be expected. It affected mainly the temporal arteries, but the facial and occipital arteries were sometimes involved too, and in about one-third of the cases involvement of the ophthalmic vessels led to blindness in one or both eyes. In a few cases seen at necropsy there had been involvement of many internal arteries as well. Clinically there was intense headache and often fever, leucocytosis (though rarely eosinophilia), and a high E.S.R. The affected arteries were thick, cordlike, and tender, and the skin might be reddened. Removal of a segment of the artery for biopsy seemed to be the most reliable method of giving symptomatic relief. Lantern plates of six cases of temporal arteritis and two cases of polyarteritis were shown to demonstrate the characteristic histology of the former (narrowed lumen, greatly thickened intima with characteristic histology, and inflammatory infiltration of media and adventitia) and the similarity of the two diseases. It was concluded that temporal arteritis was a characteristic disease both clinically and pathologically, but that it resembled polyarteritis enough to justify the view that they might be of similar aetiology.

Professor BERGSTRAND believed that temporal arteritis was merely a form of polyarteritis, and Professor PULVERTAFT recalled two cases of temporal arteritis, one of which had eosinophilia.

Vascular Changes in Diabetes

Discussing the vascular changes in diabetes, with particular reference to the renal and retinal vessels, Dr. NORMAN ASHTON (London) compared the histopathological changes in the retina with the general vascular condition and the kidney lesions in 32 fatal cases of diabetes. With the aid of new staining methods, particularly the periodic acid technique of oxidizing polysaccharides to polyaldehydes and then staining with fuchsin-sulphite, he showed, with a series of coloured lantern slides, that the essential lesion was a capillary microaneurysm confined to the retinal vessels and chiefly localized in the posterior polar region in the capillaries which link the deeper and more superficial plexuses. He compared the occurrence of this retinopathy, graded according to severity, with the presence of intercapillary glomerulosclerosis, and found that the more severe the retinopathy the more constant was the association with this particular renal lesion. The two conditions were manifestations of the same pathological process modified by different anatomical structures. He hoped that histochemical methods would be used to find if the waxy exudate in the retinopathy was the same as the hyaline material in the glomerulosclerotic lesion. Professor K. R. HILL believed that the hyaline masses in the glomerulus in intracapillary glomerulosclerosis were in fact microaneurysms, as could be shown by serial section.

SECTION OF RADIOLOGY

Friday, July 1

Radiology of Joints

Under the chairmanship of Dr. C. G. HITCHCOCK (Harrogate), vice-president, a discussion took place on the radiology of joints. Dr. E. DUFF GRAY (Manchester) said that in the radiological examination of joints the following features required individual study: (1) The "joint-space," (2) the articular surfaces, (3) the architecture and density of the neighbouring bones, (4) the para-articular soft tissues, and (5) the effects of movement and posture. The routine radiographic projections were well known and had become largely standardized; their aim was to show as much bone-free joint-space as possible and to demonstrate the relationships of the opposing articular surfaces. The true joint-space was not normally seen, but could be readily demonstrated by the special technique of "arthrography," and might be occasionally visible when conditions were suitable for the "vacuum phenomenon." The density of the bones near a joint might be estimated by the simultaneous exposure of a similar bone embedded in a special medium to represent the soft tissues in the living subject or by the densitometry readings of a selenium cell with comparative readings of graduated ivory cylinders. The effects of movement and posture had not yet been fully studied radiologically. Lateral films of the cervical spine in flexion and extension seemed to provide a fruitful field for inquiry. A special method of using tracings from such films allowed a ready appreciation of the extent and type of the movement taking place at each vertebral level. It seemed likely that the cervical spine was an early site for rheumatoid arthritis, and its involvement might be indicated by the radiological demonstration of abnormal movement at one or more levels. In the study of joint lesions *x*-ray examination of parts of the body other than the affected joints might be useful, and in the search for a "toxic focus" a wide range of radiological methods was employed. The interpretation of abnormal radiological findings required in most cases a consideration of the history and the clinical picture, because the *x*-ray appearances of joint lesions were rarely specific.

Dr. J. B. KING (Edinburgh) spoke of various respects in which the radiologist could afford more help to the orthopaedist. Everybody who had worked on the subject of degenerative arthritis—a term which he preferred to osteoarthritis—agreed that there was a hereditary predisposing factor in its development, but no attempt had been made scientifically to ascertain to what extent hereditary and acquired factors existed in different individuals. An American observation had shown that identical twins later in life showed similar degrees of costal-cartilage degeneration. This suggested a possibility for research. It might be useful to *x*-ray the cervical spine in a series of identical twins—a fair number would have to be taken because of the likelihood that in many cases the hereditary condition would be obscured by the result of trauma, including the trauma of gravity—and to ascertain to what extent the joints of twins showed similar degenerative arthritis.

After Dr. J. H. WILDING (Manchester) had given a demonstration of the radiological appearances in various conditions of the knee-joint, Dr. J. BLAIR HARTLEY (Manchester) spoke of a certain drifting apart of orthopaedic and radiological departments. Discussions between radiologists and orthopaedic surgeons ought to be more frequent. The radiologist did not always assist the orthopaedic surgeon as he might. How often, for example, was the orthopaedic surgeon presented with pictures of the ankle-joint or joints of the foot taken with the patient lying down, which must be useless when the case was one of flat-foot? An obligation which he always imposed upon himself was to *x*-ray the opposite—i.e., the normal—joint as well as the joint affected. On one point he differed from the opener, who had said that it was in the cervical spine that rheumatoid arthritis began; in his own observation rheumatoid arthritis attacked the cervical spine late.

Dr. R. FAWCITT (Ulverston) said that radiologists saw as patients very few of the people of whom they took radiographs, and if the orthopaedic surgeon would take a little more trouble to tell them something about the patients it might result in

ON GUARD in tinea territory

Activity is on the increase in swimming pools, baths and other centres of communal activity where the organisms responsible for mycotic infections find their hosts. Key measures to efficient control of such infection are prompt treatment of the developing case and planned protection among likely contacts . . and in both roles Mersagel is equally effective. Mersagel contains the powerful fungicide, phenylmercuric acetate, in a special water-soluble jelly base. It acts directly against the infecting fungi and maintains intimate contact with the seat of infection. Colourless and therefore clean to use, Mersagel does not normally irritate the skin and is suitable for the patient's personal application

'VOLPAR'
TRADE MARK

VOLuntary PARenthood

A report (Human Fertility, Vol. 6, No. 1, p.1) upon the times taken by fifteen different chemical contraceptives to effect complete immobilisation of spermatozoa demonstrates, clearly and decisively, the effectiveness of 'Volpar' preparations; indeed, the results of the investigation proclaim the supreme position held by 'Volpar' when classed according to its spermicidal activity. Moreover this classification is reflected in the confidence placed in 'Volpar' Gels and in 'Volpar' Paste, both in the clinics and by the medical profession.

A specially designed 'Volpar' Applicator is now available for those patients who prefer to use 'Volpar' Paste instead of 'Volpar' Gels.
For maximum safety 'Volpar' Gels or Paste should be used with a cap or sheath.

Specimen packings of 'Volpar' Gels or Paste will be forwarded to physicians on request.

VOL/E/26

SAFE Persomnia TRADE MARK (TABLETS) OR BARBITURATES?

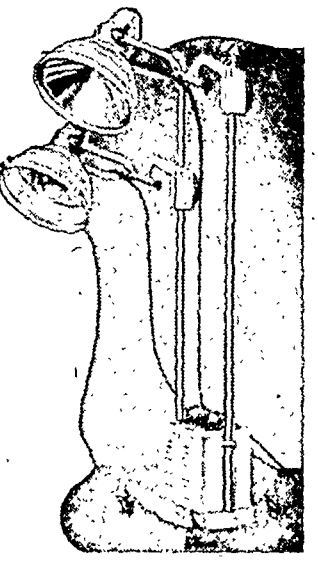
The frequently reported losses of barbiturates announced by the B.B.C. are considered to be, more often than not, attempts by addicts to obtain additional supplies of the drug.

The best means to stop such undesirable practice is to restrict prescriptions of barbiturates to the comparatively few cases which are not likely to respond to the group of sedatives known as—"*open-chain ureides.*"

Persomnia tablets, a combination of two *open-chain* ureides — bromisovalerylurea and carbromal—have been proved by long clinical practice to be as effective as barbiturates in practically all cases in which a sedative or mild hypnotic is indicated. The preparation discloses a marked synergistic enhancement of effect when compared with the therapeutic action of the two component drugs employed *separately.*

Some of the advantages of PERSOMNIA tablets are the following:

- *Not a barbiturate*
- *No bromism*
- *Not habit-forming*
- *Not cumulative*
- *No after-effects or secondary reactions*
- *Rapid induction — no preliminary excitement*
- *No nervous, hepatic or renal impairment*
- *Well tolerated even by children*
- *Absorption and excretion at optimal rate*
- *Safety in use*
- *No contra-indications are known*



NOTE :—Persomnia Tablets are prescribed under the N.H.S.

Free clinical samples and literature will be gladly sent on request.

Ensign **X-RAY FILM**

2 ways to better results

STANDARD

Ensign "Standard" X-Ray film gives outstandingly good results in Radiography of the lungs. Its fine definition, good contrast and freedom from fog are greatly appreciated in this branch of radiography.

RADOS (Non Screen)

Orthopaedic Radiography requires the extra speed and full gradation of Ensign "Rados" non-screen film. Like all Ensign X-Ray film it is extremely flexible, giving exceptional latitude in the matter of exposure on varying types of equipment.

FOR MAXIMUM DIAGNOSTIC VALUE

ENSIGN ROSS LTD. LONDON E 17

B.M.J.

more helpful positioning and radiography. Dr. J. L. A. GROUT (president of the Section) said that his impression was that ankylosing spondylitis started not in the cervical spine but in the sacro-iliac joint, and this joint should always be included in the examination. He had recently visited a steel firm which had a 400-kV machine for the *x*-ray examination of its material, and he found that they were accustomed always to take eight projections; for the human being it was customary to make use of only two films—antero-posterior and lateral. Dr. LEO DELICATI (Buxton) believed that ankylosing spondylitis and rheumatoid arthritis were the same disease in two different forms. Motion films would be extremely valuable in the elucidation of many points concerning joint structure and aberrations. Dr. J. ALEX THOMPSON (Harrogate) urged the formulation of a standard technique, with standard screens and probably standard exposures based upon the thickness of the part, so that early rarefaction of the bone might be better recognized. It was absurd to have exactly the same technique for the delicate hand of a lady and the thick hand of a labourer.

Dr. W. R. MITCHELL (Northampton) spoke of the problem of detecting very early changes in the articular cartilage of the patella. One of his own early cases had no significant bony change, but the patella showed a frond-like process 2 cm. long. He had no doubt that many arthritic conditions which they were called upon to treat in people over the age of 40 did start in the adolescent years with this peculiar condition of the articular cartilage of the patella, which did not seem to be found in other joints. As an orthopaedic surgeon he had been surprised not to hear more about cineradiography of joints.

SECTION OF SURGERY

Friday, July 1

Pain in Right Iliac Fossa

With the president, Mr. T. V. PEARCE (Harrogate), in the chair, Dr. A. FULLERTON (Batley) opened the discussion by referring to pain in the right iliac fossa as the Cinderella of the abdomen, with the appendix and the right ovary in the roles of the ugly sisters. Pain in general was classified as physiogenic (visceral, referred, and somatic) and psychogenic (anxiety, hysterical, and so on). Visceral pain was due to interference with the blood supply of a viscus, referred pain to deep-seated stimulation of cerebrospinal sensory nerves, anxiety pain to fear, and hysterical pain to a craving for sympathy. If pain in the right iliac fossa, present for more than a week, was due to appendicitis, a lump would be palpable. Chronic pain in the right iliac fossa was never due to appendicitis, or to adhesions, or to a right ovary free from demonstrable disease. Visceroptosis never caused pain in a patient whose autonomic nervous system and emotional reactions were well balanced. In distinguishing between physiogenic and psychogenic pain, age, sex, fertility, emotional conflict, and duration were important, and the prognosis of a psychogenic pain depended on its duration. Appendicectomy was advised for psychogenic pain in the right iliac fossa to remove anxiety about appendicitis. It relieved the doctor of the need to consider appendicitis at each outburst of functional pain, and gave an opportunity for complete exploration of the abdomen to exclude organic disease.

Professor DIGBY CHAMBERLAIN (Leeds) said that when a surgical opinion was sought it was usually with the idea of deciding whether or not pain in the right iliac fossa was due to appendicitis. Surgeons had tried to impress on the general public that that kind of pain might be due to appendicitis, and had been so successful that the public now almost regarded pain in the right iliac fossa and appendicitis as synonymous. Appendicitis might be acute, recurrent, or chronic. Chronic appendicitis was not characterized by chronic pain in the right iliac fossa, and the term "grumbling appendix" was a bad one, had no pathological basis, and should be discarded. In chronic right iliac fossa pain, when the diagnosis was in doubt, there was rarely urgency; in occasional cases, when doubt continued and operation was considered desirable, an exploratory laparotomy should be done and not an appendicectomy through a limited incision.

Mr. KENNETH BOWES (London), discussing the gynaecological aspects of the subject, said that pain from the ovary was referred to the tenth dorsal nerve and pain from the tube to the eleventh, so that the territories of surgeon and gynaecologist overlapped. When consulted, the gynaecologist might find some definite pathological condition of uterus, ovary, or tube, but often he found either no lesion at all, or else one of those pelvic conditions which are neither well defined nor well understood. Endometriosis in the infertile woman of over 30 caused recurring attacks of pain on one or other side, often referred down the inner aspect of the thigh, premenstrual, and relieved by menstruation. Absence of physical signs did not exclude endometriosis; sometimes a palpable swelling followed the onset of symptoms by several months. It was now known that endometriosis was common in the twenties, and 4% of affected women were in the 'teens, so for this reason alone a diagnosis of neurosis must be made with caution. In the treatment of endometriosis, conservatism should be exercised towards ovarian tissue. Partial resection was preferred to oophorectomy.

Straight *x*-ray examination was sometimes of value in revealing ossification in a dermoid—a common cause of continuous pain, with acute exacerbations if torsion occurred. Intermenstrual pain (*Mittelschmerz*) particularly masqueraded as appendicitis if accompanied, as it commonly was, by low pyrexia at ovulation. In the middle-aged woman persistent and rather vague pain suggested carcinoma of the ovary and required urgent treatment, for pain meant penetration of the ovarian capsule. A history of menorrhagia with chronic and usually bilateral pain in the abdomen, together with a tender swollen tube felt on palpation, was characteristic of chronic salpingitis.

A less definite group of patients presented in the adult sex-functioning age period with evidence neither of inflammation nor of any other definite single pathological condition. Pain was referred low in one or other iliac fossa, but usually the right, and there was low backache and dyspareunia. The pain, which was premenstrual, was increased by effort, standing, or emotional strain. Intermittent attacks of acute pain might simulate appendicitis but were accompanied by agitation and emotional reaction. On physical examination there might be tenderness in an ovary or lateral to the cervix, which might be infected. There might be urinary symptoms too, or mammary discomfort, or such psychological concomitants as insomnia, frigidity, headache, or excessive fatigue. Fertility was often low. It was unlikely that psychological disturbance was alone to blame. Disturbances in pelvic circulation might be important, for they could be effected by gravity, bowel function, endocrine influences, and nervous stimulation. Such patients did not require surgical intervention.

Mr. G. H. MACNAB (London), considering right iliac fossa pain in childhood, said that the frequency of abdominal pain in childhood was due to immaturity of the lymphatic system, which seemed over-responsive to infection. He gave a clinical description of abdominal lymphadenitis, non-specific and tuberculous. Mr. M. W. C. OLDFIELD (Leeds) recalled the observation of Braithwaite that an enlarged lymph node could cause pain mechanically, its rough surface scraping over adjacent peritoneum. Mr. PHILIP TURNER (London) added Meckel's diverticulum to the list of causes of pain in the right iliac fossa previously considered, and described two cases of that condition. Spasm of the colon and orchitis in an abdominal testis might also cause right iliac fossa pain on occasion. Mr. IAN FRASER (Belfast) described chronic appendicitis as a sociological phenomenon because of the present pressure on hospital beds. He disagreed with a previous speaker about the age at which the abdominal lymphoid tissue reached full development; in his view that tissue was enormous in quantity, particularly in the young child.

Mr. DICKSON WRIGHT (London) recalled that tragedies had occurred from concluding that a child suffering from tonsillitis and abdominal pain must be suffering from lymphadenitis rather than the appendicitis which was really present. He also disagreed that castor oil was dangerous in itself; it was the delay associated with purgation rather than the purgation itself which was important. He could not believe that the removal of a normal appendix was ever followed by

lifelong invalidism, and he had no hesitation in performing appendicectomy if the diagnosis was doubtful. He used at operation a small incision, big enough only to introduce a finger into the pelvis and to withdraw the ileum for the detection of a Meckel's diverticulum. Girls in the late 'teens suffering from right iliac fossa pain were a common problem and were best treated by appendicectomy. Mr. T. V. PEARCE, the president, recalled from his experience some rare causes of pain in the right iliac fossa. There was a remarkable case of mediastinal abscess, consequent on quinsy, which pointed as a psoas abscess in the right iliac fossa.

Dr. FULLERTON, replying, had found that a tender spot above and to the left of the umbilicus (Power's point) was commonly present in cases of adenitis.

SECTION OF CARDIOLOGY

Friday, July 1

Simulation of Heart Disease by Other Conditions

Dr. RAE GILCHRIST (Edinburgh), in discussing common errors in diagnosis, said that he believed that many mistakes could be avoided if more time were spent in obtaining an accurate history, and particularly in paying attention to the manner in which the story was told. This applied especially to the interpretation of symptoms such as pain. Angina pectoris, for example, had to be diagnosed entirely on the history, not by physical signs. When a patient complained of pain in the chest the chances were that it was not angina pectoris or any other organic disorder. If a person was able to take a brisk walk on a cold day one could be fairly confident that angina was not present.

The speaker then discussed the differential diagnosis between cardiac infarction and massive pulmonary embolism. He stressed that (1) a patient in bed or during convalescence on account of some other illness was far more likely to develop pulmonary embolism than cardiac infarction; (2) the onset of symptoms was abrupt in pulmonary embolism, and they reached their maximum severity at once, whereas in cardiac infarction there was often delay before the symptoms reached their peak; (3) pain in massive pulmonary embolism was admittedly central, but did not, as a rule, radiate; moreover, it was rarely severe, being more properly described as distress from suffocation; (4) in pulmonary embolism, dyspnoea was sudden and intense, whereas in cardiac infarction it was rarely conspicuous at the onset. The distinction could usually be made clinically, although the electrocardiogram was helpful in doubtful cases.

Dr. Gilchrist then turned to physical signs. He had found that hypotension often gave rise to anxiety and that the significance of a fall in pressure following cardiac infarction was apt to be overemphasized. This fall was often only slight and in some cases did not occur at all; on the other hand, low blood pressure frequently resulted from long-continued sepsis or other infection. Oedema was caused by many agents other than heart failure; and in the absence of dyspnoea it was rarely cardiac in origin.

Speaking more generally, Dr. Gilchrist emphasized the importance of avoiding terms like "fatty heart": it was better to tell an obese patient that he had a Rolls-Royce engine but that the bodywork was poor. It was important to weigh the patient. A neurosis could be detected by studying the patient's personality; organic heart disease was rare without dyspnoea; it was often more important to measure the haemoglobin than to take an electrocardiogram; and, finally, fewer mistakes would be made if the physician always demanded an aetiological diagnosis. Even so there was a borderline group in which it was by no means easy to be sure whether there was organic heart disease or not. There was Gowers's syndrome, characterized by weakness, prostration, and bradycardia lasting half an hour or so, in middle-aged women—Ryle's vaso-medullary storms; and there were cases of apparent heart failure in pregnancy in which follow-up studies showed no evidence of heart disease. In fact, in 380 follow-up examinations of cases of heart disease detected in pregnancy 10% appeared to be normal subsequently.

Dr. J. CLIFFORD HOYLE (London) dealt with the simulation of heart disease by pulmonary disease. Purulent sputum was never cardiac in origin. Cough was dominant in heart disease only in the presence of congestive heart failure, gross cardiac enlargement, or aneurysmal dilatation of the left auricle, pulmonary embolism, or pericarditis. Dyspnoea could rarely be ascribed to disease of the heart if that organ was not enlarged, and it was rare for patients with bronchial asthma to develop cor pulmonale. He also stressed the absence of electrocardiographic changes in cases of dyspnoea due to pulmonary disorders.

Paroxysmal dyspnoea, though suggestive of left ventricular failure, might also be due to bullous disease of the lungs or to partial bronchial stenosis with recurrent collapse. Haemoptysis appeared late in heart disease, whereas it often complicated the earlier development of pulmonary disease. Pain radiating into the left shoulder and arm might be due to apical pleural adhesions, and sternal pain might result from mediastinal tumours.

In radiological differential diagnosis Dr. Hoyle pointed out that difficulty might arise in distinguishing between dilated pulmonary arteries and hilar adenopathy, and between the appearances of lymph stasis associated with sarcoidosis, for example, and pulmonary congestion in mitral stenosis, particularly when associated with haemosiderosis; and finally between neoplasm or other space-filling tumours and aneurysms.

Dr. S. W. PATTERSON (Ruthin Castle) discussed the simulation of heart disease by intestinal disease. He lent support to the old aphorism about patients complaining of indigestion having heart disease, and vice versa. He described the painful effects of diaphragmatic hernia, and pointed out that dyspnoea and sweating might accompany attacks. Such pain, however, was not closely related to effort. Breathlessness might be due to the anaemia associated with a bleeding ulcer, gastric neoplasm, or haemorrhage from bleeding haemorrhoids. Vomiting and collapse due to food poisoning was sometimes mistaken for coronary thrombosis.

He went on to discuss reflex disturbances of cardiovascular function, and quoted a case of paroxysmal tachycardia cured by appendicectomy. He showed electrocardiograms and graphic records of respiration and blood pressure illustrating cardiorespiratory dysfunction resulting from oesophageal, gastric, biliary, or colonic distension. Psychosomatic cardiovascular disturbances should not be confused with reflex disorders of the type described.

Dr. WILLIAM PHILLIPS (Cardiff) described the simulation of heart disease by psychoneurosis. Numerous vague and indefinable symptoms, especially faintness, dizziness, palpitations, weakness, exhaustion, and left inframammary pain, were commonly psychoneurotic. In the history of man most of the common emotions had been described in terms of the heart. It was not a bizarre situation that mattered most in psychiatric aetiology, but the ordinary day-to-day disappointments, difficulties, and anxieties. Frequent sighs and inability to take a deep breath were always psychiatric in origin. The only common symptom of organic heart disease was pain or breathlessness on effort; psychoneurotic pain or breathlessness was far less closely related to exertion.

Psychoneurosis might be referred to the cardiovascular system: (1) because innocent symptoms were attributed to the heart by either the patient or his doctor; (2) following a cardiac illness or death in the family or in the patient's circle of friends; (3) because of incautious statements or actions by medical advisers; (4) because there had been no proper reassurance. He thought that 90% of these difficulties would be resolved if there were sufficient time to take a proper history and to study the patient as a human being. Physicians must insist on a full aetiological, structural, and functional diagnosis of organic heart disease; terms such as "tired," "fatty," or "strained" heart should be condemned.

Obstinate Heart Failure

Dr. D. EVAN BEDFORD (London) opened this discussion by defining the term "obstinate heart failure." He considered it meant congestive heart failure with oedema continuing in

patient at rest in bed and despite routine therapeutic measures, including digitalis, mercurial diuretics, and limitation of salt and water; or a similar situation recurring as soon as a patient became ambulant; or persistent left ventricular failure or elevation of the venous pressure and enlargement of the liver without oedema in similar circumstances. The first consideration was to make sure that no aetiological agent which could be corrected was responsible, such as thyrotoxicosis, anaemia, avitaminosis, and Pick's disease. The next step might be to put the patient into a wheel-chair, for it was possible to keep a patient in bed too long. Phlebothrombosis with recurrent pulmonary embolism was encouraged by prolonged recumbency. Dr. Bedford had never been convinced that anything could be gained by giving mercurial diuretics more often than twice weekly; but in cases of obstinate ascites the intraperitoneal route was sometimes helpful; another variation that might help was to change from "neptal" to mersalyl or vice versa when the response became poor. Mechanical drainage of fluid through incisions made over the dorsum of the foot was advised in cases of persistent dropsy. The patient should sit in a chair with the legs down not only while the fluid was draining away but also beforehand, so that the legs were tense before the incisions were made.

A low sodium diet was undoubtedly of great benefit. In an ordinary hospital light diet 3–5 g. of sodium could be expected; sodium could be reduced to 2–4 g. by eliminating table salt and cooking salt; but this was not enough, for less than 2 g. of sodium per day was required. Bread and butter were the chief difficulties in London. The Karrell diet, consisting of 900 ml. of skimmed milk per day, contained 0.4 g. of sodium. The Kempner diet, consisting of rice, fruit, and sugar, contained only 0.15 g. of sodium per day. Modified diets could be arranged of 1,000–2,000 calories, containing from 0.5–2 g. of sodium per day, and these were very helpful in prolonged treatment; but a low calorie diet was often beneficial in itself.

With ambulant patients a close watch should be kept on their weight, and effective treatment should not be withheld until oedema was manifest. Dr. Bedford then discussed the results of therapeutic myxoedema, induced either by means of total ablation of the thyroid gland or by thiouracil derivatives. Myxoedema benefited cases of heart failure not only by reducing the oxygen requirement and therefore the work of the heart, but also by lowering the heart rate. The latter applied particularly to cases of auricular fibrillation or flutter in which the heart rate could not be properly controlled by ordinary means. Therapeutic myxoedema was far less helpful in cases of obstinate oedema than in patients with persistent left ventricular failure or intractable angina. The results of total thyroidectomy were probably better than those with thiouracil, and the mortality rate was not higher. He had used methyl thiouracil in doses of 600 mg. daily in 35 cases of persistent heart failure with good results in 50%; three developed agranulocytosis, and one of these patients died.

He did not object to patients prescribing vitamin E for themselves, for he felt fairly confident that it did them no harm. He used anticoagulants for those with phlebothrombosis. Recent surgical measures devised for particular situations were mentioned. They included ligation of the inférior vena cava and tricuspid valvulotomy for patients with severe pulmonary congestion; anastomosis of a pulmonary vein to the azygos vein in cases of severe mitral stenosis with recurrent attacks of pulmonary oedema; and mitral valvulotomy.

Dr. D. R. CAMERON (York) described the low sodium diet and the results of this treatment in greater detail. He had been able to obtain salt-free bread and butter in Liverpool and admitted that this eased the difficulties in arranging a suitable diet. He was able to provide for these patients 2,000 calories daily containing only 0.4 g. of sodium. In cases of congestive heart failure under control the addition of 2–5 g. of sodium chloride daily caused a demonstrable rise in body weight within a few days. With a satisfactory diet the daily excretion of sodium chloride should not exceed 1–2 g.; using a strict Kempner diet it rarely exceeded 0.25 g. A series of charts were shown illustrating not only the proof that a low sodium diet was beneficial but also the difficulties that were met in coming to such a conclusion.

SECTION OF DERMATOLOGY

Friday, July 1

Psoriasis

With the president, Dr. J. T. INGRAM (Leeds), in the chair, Dr. H. W. BARBER (London) in a stimulating and provocative opening paper stressed the similarity between the problems of psoriasis and of rheumatoid arthritis. He would not exclude the possibility of a specific infective organism such as a virus playing an important part in the aetiology, as in herpes simplex. The weight of evidence, however, was in support of psoriasis being a non-specific reaction of the skin to various kinds of stress in persons with an inborn tendency to that pattern of reaction. There was no specific treatment for psoriasis. The work of Danysz, who produced a variety of non-specific diseases in experimental animals by repeated injection of a foreign protein, was discussed. The particular "target organ" which reacted was specific for the individual. The work of Selye with pituitary and adrenocortical extracts was important, and his term "diseases of adaptation" was very apt.

The relationship of psoriasis to rheumatic fever in childhood and to rheumatoid arthritis, gout, and other "rheumatic conditions" in the adult was considered, and also the occasional association with so-called allergic diseases. Age at onset, race, and climate were all significant. Among the many factors which might be operative in the aetiology of psoriasis attention was drawn to the influence of infections, especially streptococcal infections. This guttate reaction to infections was seen particularly in children. The influence of the menopause in provoking a particular pattern of psoriatic reaction was noted; other influences, such as errors of metabolism and shock or emotional disturbances, were important provocative factors. Pregnancy and jaundice commonly had a temporary beneficial effect upon the course of psoriasis and of rheumatoid arthritis. The association of psoriasis with rheumatoid arthritis was a recognized syndrome. Gout with secondary osteoarthritis when associated with psoriasis gave a very similar picture.

Dr. Barber described two patients in whom the ingestion of cow's milk seemed to be responsible for the eruption of psoriasis, and he felt that the question of food allergy called for further research. Each case of psoriasis had to be considered individually, and if the provoking cause or causes could be determined in a particular case there was a good chance of successful treatment.

Dr. BRIAN F. RUSSELL (London) took the view that the psoriatic state, often latent, was hereditary and probably indicated some error in fat metabolism not yet elucidated. This underlying state, however, might not call for treatment; it was the provocative causes of exacerbations of the condition which had to be treated. In this regard two large groups were those cases following infective states and those associated with psychogenic disturbances. In the latter group the eruption was often of flexural distribution; it would seem that pruritus was commonly the primary symptom and psoriasis appeared secondarily as the result of friction.

Psoriasis was a skin reaction to a wide range of stresses, including all grades of physical injury, lack or excess of sunlight, cold, fatigue, infections, bacterial toxins, drugs, emotional difficulties, and endocrine disturbances. The skin was the organ which suffered, because of an inherited biochemical fault resulting in defective keratinization, a fault which was latent until aggravated by one of these stresses. The stresses were similar in nature to those which might excite rheumatoid arthritis. The tendency in both disorders to spontaneous remissions and relapses, improvement in pregnancy, and response to non-specific measures all seemed to support the possibility that they might both arise from repeated stimulation leading to failure of adaptation in the endocrine–autonomic system.

Dr. J. H. TWISTON DAVIES (Manchester), commenting on Dr. Barber's consideration of the arthropathic forms of psoriasis, drew attention to analogies in other dermatoses. He discussed the generalized form of guttate psoriasis of isolated or seasonal occurrence and its possible relationship to what he termed "seborrhoea." He criticized the conventional classification of

skin diseases. He agreed that psoriasis could sometimes be cured, but felt that in many cases it was better for the patient to adjust his emotional reaction to the infirmity rather than labour with the conventional lines of treatment. He stressed the difficulty of assessing the value of physical and chemical methods of treatment.

In a lively discussion which followed the opening papers Dr. HERBERT BROWN (Glasgow) compared psoriasis of the vulva and peri-anal regions with neurodermatitis in these sites and thought they were often of similar significance; *x*-ray therapy was often useful. Dr. G. A. GRANT PETERKIN (Edinburgh) recognized heredity and trauma as playing a part but raised the question of a filterable virus and quoted cases suggesting contagion. He thought that psoriasis in hot countries was caused by sweating and friction. Sir Norman Walker had employed the "so-called" Goeckermann treatment many years ago. Dr. F. F. HELLIER (Leeds) thought that treatment which included sunlight therapy increased the patient's resistance and diminished the possibility of relapse. Dr. G. HODGSON (Cardiff) said he had seen the part played by trauma as an aetiological factor in mine workers. Dr. MARY SMITH (Glasgow) suggested that those who did not tan were more readily affected, but Dr. A. BIGHAM (Bradford) said he had seen many cases of psoriasis in coloured troops in India.

Dr. H. R. VICKERS (Sheffield) had found thorium X of value in psoriasis of the scalp, and Dr. W. N. LEAK (Winsford) put in a plea for dithranol to be prescribed in cream bases in tubes so as to reduce the staining of clothes. Dr. S. T. ANNING (Leeds) protested against the psoriatic patient being left untreated. Dr. J. T. INGRAM (Leeds) mentioned a patient who had been under his care in infancy with eczema, at 7 years of age with alopecia, and now at 14 for psoriasis. Others who contributed to the discussion were Dr. C. D. EVANS (Bristol), Dr. MCKINLEY (Derby), and Dr. A. J. E. BARLOW (Huddersfield).

In reply Dr. BARBER said that, while a first treatment with *x* rays was often effective, subsequent treatments were not. He stressed the importance of focal infection and quoted the analogous relationship in tuberculide and dermatophytide reactions.

Use and Abuse of Chemotherapy

Dr. F. F. HELLIER (Leeds) introduced a discussion on chemotherapy in dermatology. Penicillin and sulphonamides were frequently prescribed when there was no justification for their use. Penicillin was probably more effective and less likely to give rise to sensitization if used as a lotion or spray. It was of value in the treatment of impetigo, ecthyma, infected ulcers, folliculitis, and sycosis. It should not be used in eczematous states even though infected. The application should be limited to a seven-day period. Sycosis often relapsed through infection being carried in the nostrils, and they should therefore receive treatment.

Parenteral therapy was suitable for deep infections; procaine penicillin was more efficient and less painful than other forms. Its use by mouth should be restricted to infants under the age of 6 months. Common reactions to the drug were erythema and urticaria, though asthma and exfoliative dermatitis might occur. Sulphonamides should not be used for local treatment for longer than five days. Internally they should be given in an adequate dosage for about five days. Sulphonamide dermatitis was now less common, but if it occurred it was very intractable. It was characterized by vesicles about the fingers suggesting a dermatophytide eruption. Recently attention had been drawn to the occasional appearance of periarteritis nodosa as a result of sensitization to sulphonamides.

Dr. P. B. MUMFORD (Manchester) did not think penicillin or sulphonamides should be used locally, and he did not regard the use of soap and water as helpful in the treatment of boils. Dr. H. W. BARBER (London) mentioned a case of periarteritis nodosa due to sulphonamides. He restricted the use of sulphonamides to a single five-day course. Dr. H. R. VICKERS (Sheffield) felt that the specialist did not see the large number of cases treated successfully by general practitioners. He saw much less pyodermia in children than previously, and he thought sensitization in children was very rare. Dr. W. N. LEAK (Winsford) suggested that the microform sulphathiazole used as a cream was more efficacious. Dr. LIPMAN COHEN (London) thought thyrotricin should replace penicillin and the sulphonamides in local therapy, as sensitization to this antibiotic was rare. Dr. P. INMAN (Sunderland) and Dr. A. CARLETON (Oxford), however, mentioned cases of sensitization to thyrotricin. Dr. A. J. E. BARLOW (Huddersfield) had seen penicillin dermatitis follow the insertion of penicillin tablets into dental sockets.

SECTION OF OPHTHALMOLOGY

Friday, July 1

Toxoplasmosis

Under the chairmanship of Mr. N. P. R. GALLOWAY (Nottingham), vice-president, a paper on toxoplasmosis was read by Mr. A. B. NUTT (Sheffield). He described the case of a 3½-year-old girl with signs of old central choroido-retinitis in each fundus together with mental backwardness. Two years previously, when he had first seen the child, a diagnosis of toxoplasmosis had not been considered, because at that time no *known* cases had been seen in this country. But the ravages of the disease might well have been misinterpreted as instances of congenital malformation or as the consequences of other infective agents. During a study visit of the Faculty of Ophthalmologists to Professor Franceschetti's clinic at Geneva last year Mr. Nutt had had the opportunity of hearing Dr. Bamatter's account of toxoplasmosis and to examine a number of cases assembled by that observer. Being struck by certain features of resemblance to his own case, Mr. Nutt had investigated the girl's case on returning to England. No radiological signs of intracranial calcification had been found, but that feature was neither pathognomonic nor invariable. Admittedly the toxoplasma had not been identified, but the intracellular protozoön was notoriously elusive, even during the acute stage of the disease. Laboratory tests, however, had given results supporting that diagnosis, towards which the clinical features had already drawn his attention.

In that case there had been no history of any severe illness before the child's vision had first been presumed to be defective, but intrauterine infection was a well-recognized mode of acquiring toxoplasmosis, and the house inhabited by her mother during pregnancy had contained a dog and was infested by mice. Mice, guinea-pigs, cats, and dogs are among the animals suspected of conveying the organism. Several cases had been reported in a family of taxidermists, and one of Dr. Bamatter's patients had been a woman whose pillow had been shared with a cat.

Clearly the problem of toxoplasmosis required further research, and so far the results of treatment had been disappointing, nor was it yet known to what extent prevention was possible. Meanwhile clinicians should bear in mind the possibility of this protozoal disease as an explanation for low-grade intelligence in association with bilateral patches of old central choroido-retinitis characterized by large size, irregular pigment proliferation, and clear-cut margins. Mr. Nutt's coloured fundus drawings clearly displayed these features, and in his case no similar lesions were present in the outlying regions of either fundus. Peripheral lesions did occur, and might reach a size many times greater than that of the optic disk. When the intrauterine devastation wrought by rubella was first revealed by Australian observers, clinicians in other parts of the world were sometimes inclined to suggest that disease as an explanation for lesions readily attributable to other maladies. The same tendency was already becoming evident with regard to toxoplasmosis. Nevertheless, the disease could no longer be dismissed as a remote possibility in Britain. Hitherto most of the cases recorded had been in inhabitants of the U.S.A. or the European mainland, and he could find only one published case in our literature at the time of reading his paper. (A report by Mr. Harold Ridley of a case of toxoplasmosis has since appeared in the *British Journal of Ophthalmology*, 1949, 33, 397.)

Ophthalmology in Spain and Holland

Mr. JOHN FOSTER (Leeds) then spoke on practical ophthalmology in Spain and Holland in 1948. He had been greatly

impressed by the speed of certain operators in Spain and Holland. At several clinics he had found that the average time spent on diathermy for detached retina was less than five minutes, and once he had witnessed fifteen intracapsular cataract extractions in three-quarters of an hour. Such speed—when it was combined with care and dexterity, as it had been on those occasions—could be achieved only by an able operator supported by first-rate assistants working in a smoothly organized theatre. Another striking feature had been the wide discrepancy between different clinics with regard to operative asepsis. Some surgeons had favoured prolonged washing of hands and forearms before donning gown, cap, mask, and gloves. Others had cared for none of these things, and purists would perhaps be horrified to hear that statistics did not reveal any corresponding discrepancy in the post-operative infection rate.

SECTION OF OTO-RHINO-LARYNGOLOGY

Friday, July 1

Respiratory Obstruction in Children

With the president, Mr. A. B. PAVEY SMITH, *in the chair*, Mr. G. E. ARCHER (Manchester) read a paper on acute respiratory obstruction in infants and young children. He reviewed some of the causes of asphyxia neonatorum, suggesting how it might be avoided and how treated, and emphasized the desirability of having a trained endoscopist attached to every obstetric unit. Nasal respiration was the natural method, and essential in newborn infants. Nasal and postnasal obstruction could therefore cause severe dyspnoea. He stressed the importance of adenoid hypertrophy in the very young, and described acute nasopharyngeal tonsillitis as a clinical entity. He discussed laryngo-tracheitis and the differential diagnosis between it and laryngeal diphtheria. He then described and differentiated spasms of the larynx due to reflex irritation, inflammatory states, or other causes, referring specially to laryngismus stridulus, laryngitis stridulosa, and nocturnal dyspnoeic attacks in children, and he emphasized the importance of other conditions, such as laryngeal diphtheria, retropharyngeal abscess, thyroid and thymic disease, and foreign bodies.

Dr. MARY J. WILMERS (London) discussed the ways in which acute respiratory obstruction presented in infants and young children. She defined four clinical groups: (1) Sudden cessation of breathing without preceding distress, as seen in "breath-holding," *laryngismus stridulus, and pertussis*; (2) laryngeal distress and stridor, the commonest cause being laryngeal diphtheria, though other causes were trauma by instrumentation, as in bronchoscopy, and oedema secondary to scalds or caused by allergy; (3) attacks simulating asthma, due to obstruction of a main bronchus by foreign body or tuberculosis; (4) variable and intermittent stridors, which were absent during sleep or rest. That included congenital laryngeal stridor, and pressure on the trachea from without by an abnormal aortic arch, retrosternal goitre, enlarged thymus, and tuberculous mediastinal and paratracheal glands. It could also occur in cases of papillomata of the larynx and of catarrhal laryngitis.

Mr. J. H. OTTY (Bradford) emphasized how rarely the laryngologist saw the condition under discussion. In a 10-year period at Bradford at the Royal Eye and Ear and the Fever Hospitals only 27 patients required tracheotomy and 10 intubation. He agreed with Mr. Archer on the importance of adenoids, but thought that in infants much help could be obtained from the use of paraffin or ephedrine drops, and from multi-vitamin therapy. He rarely found it necessary to curette the adenoids before the age of 3 or 4 years. Acute retropharyngeal abscess was becoming very rare, and acute laryngeal obstruction by papillomata was extremely rare. He looked forward to the day when fever hospitals would become part of the general hospital system, so that endoscopists would be readily available to them.

Dr. E. C. BENN (Leeds) ascribed the unusual fall in the incidence of laryngeal diphtheria to the type of bacillus. The most important cause of mortality in tracheotomized diphtheria patients was toxaemia. Among the fevers measles now was the commonest cause of laryngeal obstruction. There was the group of varying and often uncertain aetiology, which included those cases of acute laryngo-tracheitis which Mr. Archer had described. He concluded by evaluating the three forms of interference available—aspiration, intubation, *and tracheotomy*.

In the discussion which followed Mr. A. S. DE B. COCKS (Adelaide, South Australia) condemned the use of metal instruments in treating cases of asphyxia neonatorum. He drew attention to the frequent cases of acute laryngo-tracheitis reported in Australia and to the almost complete disappearance of diphtheria in S. Australia. Dr. H. M. JAY (South Australia) described the epidemic of acute laryngo-tracheitis in more detail. All cases were thought at the time to be laryngeal diphtheria, and almost all were fatal from toxaemia. Mr. W. J. DAGGETT (London) strongly deprecated the use of endotracheal anaesthesia in infants.

Dr. J. F. BIRRELL (Edinburgh) stated that the commonest cause of death from respiratory obstruction in infants in the Sick Children's Hospital in Edinburgh was the inhalation of vomit. Treatment by bronchoscopic suction had succeeded in a few such cases. Congenital laryngeal paralysis with associated sensory changes was sometimes a cause. He advocated tracheotomy in cases of obstructing laryngeal papillomata, and favoured removal of adenoids, when necessary, in very small infants. Dr. S. DEBONO (Malta) described an epidemic of laryngo-tracheitis occurring in Malta last winter, and the treatment by direct laryngoscopy and aspiration, with the *administration of streptomycin*. Dr. A. P. M. PAGE (Nottingham) disagreed with giving carbon dioxide to babies. He thought the condition described by Mr. Archer should be called acute laryngo-tracheo-bronchitis, and that it was the extension into the bronchioles and not the toxaemia which killed. Palpation was important in the diagnosis of retropharyngeal abscess.

Mr. T. McM. BOYLE (Leeds) asked if cases of pertussis developing stridor should be treated in the decompression *chamber*. Dr. H. STANLEY BANKS (London) thought that laryngo-tracheitis comprised two or more conditions, either of bacterial or of virus origin. Tracheotomy did not save these patients, nor did chemotherapy. Two fatal cases showed well-marked haemorrhagic pulmonary oedema. The decompression chamber was of no value in treating early pertussis and its complications.

Dr. W. M. JONES (Harrogate) said that most cases of asphyxia neonatorum were due to drugs and anaesthetics given to the mother. Mr. PAVEY SMITH, the president, agreed that tracheotomy in diphtheria was becoming ever rarer. He advocated intubation of the larynx by a gum-elastic catheter under direct vision as the first step in performing tracheotomy. Mr. ARCHER, in reply, agreed that tracheotomy in young infants was an *exceedingly difficult operation. Anaesthetists should be trained* to realize the possibility of damaging the delicate structures of the infant larynx. Laryngo-tracheo-bronchitis had been discussed at some length, but he had seen only four cases, two proving fatal; and in these the oedema present was tracheal and not laryngeal.

CLINICAL DEMONSTRATIONS

On the afternoons of June 30 and July 1 demonstrations were arranged at the Royal Bath Hospital. A large number of patients suffering from osteoarthritis, ankylosing spondylitis, and rheumatoid arthritis were shown in various stages of recovery following surgical procedures. Some of them were still bed cases, others were on crutches or could walk unassisted, some even entered the hall on bicycles, and so right up to apparent full recovery of function. Mr. H. PETTY (Leeds) was in charge of the demonstration, which was followed by a film. The physiotherapy regime for cases of cup arthroplasty was demonstrated. The patient was put on a Thomas splint with skin traction, and passive movements were instituted with the aid of a cord passing through pulleys and attached to the splint. The Thomas splint was taken off at the fourth week, a foot splint used, and the exercises continued. By the eighth week there was progress to crutches, and the patient was shown to be capable of performing certain special exercises.

Obituary

Dr. H. Bruce Low writes: As an intimate friend of HENRY ANSTEY COOKSON may I add a few words to the tributes already paid to him (June 11, p. 1055)? Cookson was richly endowed and had unusually varied opportunities for gaining experience. He was pathologist to a busy provincial hospital, and material from other hospitals in a thickly populated industrial area was sent to him; all of which made him claim to be essentially a clinical pathologist. But he became also an expert in forensic medicine, and coroners' and judicial courts relied to an increasing extent on his investigations and testimony. His attainments were recognized by his colleagues in Edinburgh admitting him without examination as a member of the Royal College of Physicians and later promoting him a Fellow. His scientific standing was acknowledged by his election as a Fellow of the Royal Society of Edinburgh.

Cookson's interests were wide. He was equally at home in discussing moths and butterflies, gannets on the Bass Rock, palaeolithic prehistory, the internal workings of a motor-car, the intellectual and cultural qualifications of bishops, or, it seemed, anything and everything. He had shrewd, wise, and provocative opinions readily expressed on any subject that happened to be mooted. He was prepared to say what districts of the country motorists had passed through by an examination of the insects adhering to their windscreens. With no parade of piety, he had definite religious convictions. He cared not whether a man was Episcopalian or Presbyterian, but he disdained any who were devoid of religious principles. Pride of race and in his country's achievements were a portion of the deeper parts of his character.

But among his friends this man, affectionately known as "Cookie," will be remembered chiefly for his boyish impishness and fun. To be in his company was a delightful entertainment. A humorous remark quickly broke through the reserve of strangers, and a picture comes to my mind of the learned scientist, sitting on his luggage in the corridor of a wartime crowded train, taking his part with a group of passengers in reading a play which a hitherto unknown fellow-traveller happened to have in his bag, the whole performance promoting hilarious enjoyment on an otherwise tedious journey. Be his desk never so high with work waiting to be done, he followed you out of his office, along the passage, down the stairs and to the outer door, firing off quips, jests, and leg-pulls that made the escape of the willing victim difficult. With all his learning and bonhomie, there was a surprising tenderness and depth of feeling for any who were in trouble. His imagination readily put him into the predicament of the unfortunate one and he was apt with sympathy and proffered help. The world of his acquaintances is left sad and impoverished by the loss of this remarkable and lovable man.

Dr. ALISTER FORBES COWAN died at his home in Lincoln on June 9 at the age of 62. For the past two or three years he had been handicapped by illness but had carried on his practice with characteristic pluck. Born in Edinburgh, he was educated at Merchiston Castle School and at Edinburgh University, where he graduated M.B., Ch.B. in 1912. He took the F.R.C.S.Ed. in 1923. After holding resident appointments as house-surgeon in the Royal Infirmary, Edinburgh, and as senior house-surgeon at the Royal Sussex County Hospital, Brighton, he joined the late Dr. F. J. Paley in practice in Hove. He served in the first world war as a captain, R.A.M.C., and subsequently migrated to New Zealand, where for some years he practised at Akaroa and had charge of the hospital there. Always interested in gynaecology, Cowan decided to specialize in this subject and moved to Wellington, but unfortunately he was soon incapacitated by illness. After his recovery he settled in Lincoln, where he practised for the rest of a busy life. Alister Cowan's buoyant and enthusiastic temperament carried him through all difficulties, and his sunny nature made him many staunch friends. He was a fine quarter-miler in his young days, and he loved every kind of sport, especially shooting, golfing, and fishing. To his widow and two surviving children, one an officer in the Gurkhas the sympathy of all his colleagues and friends will be extended.—H. N. F.

Dr. LAURENCE SEBASTIAN MORGAN, of Grenada, British West Indies, died at Virginia Water, Surrey, on June 9, aged 6[illegible] years. He was the elder brother of Dr. H. B. W. Morgan, M.P. for Rochdale. He qualified later in life than usual, and after short service in the R.A.M.C. in the 1914–18 war (from which he was invalided) he returned to the Caribbean area and joined the Colonial Service. He was stationed for the remainder of his life in the Colony of Grenada and its satellite islands, and did at different periods many malarial surveys for the Government. He was secretary, and later president, of the Grenada branch of the B.M.A. Finally he acted as chief medical officer, medical officers of prisons, and principal medical officer of the asylum and quarantine station until his resignation. He was buried in Highgate Cemetery, London, after a service at the Dominican Church, Southampton Road, Hampstead.

Dr. CHARLES MORTON GAVIN ELLIOTT died suddenly on June 10 at the age of 68. He was born in Geraldton, Western Australia, and educated at St. Peter's College, Adelaide. He started work in a shipping firm, but gave this up to study medicine at Edinburgh. He took the Scottish triple qualification in 1914, and was a house-surgeon at the Royal Infirmary, Edinburgh. Afterwards he worked as an assistant to Dr. Ronald of Larbert. On the outbreak of war in 1914 he joined the R.A.M.C., and served in France for four years. He was twice mentioned in dispatches. After the war he returned to Edinburgh to take his D.P.H. in 1919, and later settled in practice in the High Street, Old Portsmouth. He built up an extensive practice, especially with Service families, and continued with his work until shortly before his death. During the recent war Dr. Elliott carried on under difficult conditions, for his house and surgery were destroyed by enemy action. A sound physician, he never spared himself in his devotion to the highest ideals of his profession and to the welfare and comfort of his patients. His qualities won him the respect and affection of all classes. He married Alison Jones, of Larbert, in 1919, and she survives him with a daughter and two sons.

Mr. HYMAN BARNETT LIEBERMAN, who died in Nottingham on June 25 at the early age of 46, was born in Sydney, Australia. He graduated M.B., Ch.M. at the University of Sydney in 1926. He then came to this country, and was appointed house-surgeon to the late Mr. A. R. Tweedie and Mr. H. Bell Tawse at the General Hospital, Nottingham. He had a natural ability for ear, nose, and throat surgery and soon decided to make this his life work. He took the D.L.O. in 1930 and the F.R.C.S.Ed. in 1932. After gaining these higher qualifications he was appointed honorary aural surgeon to the Mansfield and District Hospital, and clinical assistant to the General Hospital, Nottingham. In 1936 he was appointed honorary assistant surgeon at the General Hospital, Nottingham, and throughout the war years, following the death of Mr. Tawse, he was in charge of the ear, nose, and throat department. Long hours of work with a depleted staff, and little leisure, undoubtedly contributed to his early death, for he never spared himself in his service to his patients. After the war he retired from the Mansfield and District Hospital in order to concentrate his work at the General Hospital, Nottingham, where he was appointed to the full staff in 1947. He always had a hankering to go back to Australia. In 1948 he resigned his appointments and travelled to Perth, where he intended to continue the practice of his specialty, but anxiety about the health of his children led to his early return to Nottingham. Not long after this his own health broke down; his death from pneumonia was unexpected and tragic. It could be said of Lieberman that he had three interests—his family, to whom he was devoted, music (he was an accomplished pianist), and his work. The esteem in which he was held by his colleagues and his patients was an indication of the character and value of his services.—G. G.

Dr. GEORGE THOMAS WILLAN, a well-known Hove practitioner, died suddenly at his home on June 24 at the age of 74. Dr. Willan received his medical education at Cambridge and Guy's Hospital, taking his B.A. in 1898 and the conjoint diploma in 1891. In his early days he was especially interested in industrial medicine, and wrote several articles for *Pitman's Dictionary of Industrial Medicine*, including those on the medical examination of employees, factory health, and factory records and statistics. During the South African war he was attached to the 17th Lancers as a civil surgeon. In the 1914–18 war he commanded the 82nd Field Ambulance in the 27th Division from 1915 to 1918. He served in Belgium, France, and Macedonia, and in 1917 was awarded the D.S.O. and mentioned in dispatches. He was invalided from Salonika in 1917. Dr. Willan practised in Carlisle and later in Milton Regis and Sittingbourne before settling in Hove. He had given valuable service to many organizations, including the South African Veterans, the R.A.M.C. Association, the Ypres League, and the St. John Ambulance Brigade. In 1935 he held the office of president of the Border Counties Branch of the B.M.A. During the recent war he was in charge of a camp reception station in Brighton. Dr. Willan was a good all-round sportsman, and enjoyed a regular dip in the sea up to the last. He is survived by his widow, one son, and two daughters. The profession in Hove has lost a fine representative of the old type of general practitioner, who will be much missed not only by his many friends and patients but also by his colleagues, with whom for many years he had worked in steady friendship. He was a good comrade who could always be relied on for help when needed.—L. A. P.

Dr. JOHN GALWEY LEEBODY, medical superintendent of Fulham Hospital and formerly medical superintendent of St. George-in-the-East Hospital, died in Hammersmith Hospital on July 2 at the early age of 49. Although he had been in indifferent health for some time, his death came as a great shock to his many friends. Leebody was born in Edinburgh, educated at Merchiston, and graduated M.B., B.Ch. at Edinburgh in 1923. He obtained the F.R.C.S.Ed. in 1936. Most of his professional life was spent in the municipal hospital service. He was a capable surgeon, but of recent years had devoted more and more time to medical administration. At work he was conscientious to a fault, never sparing himself and doing everything he could for his patients and for the East End Hospital he loved. The hospital building was badly damaged during the war, and the anxiety of these years was no doubt an added strain on his health. Leebody was a man of high integrity and infinite charm who endeared himself to all who knew him. He was an ideal companion, quick with the happy phrase that neatly sized up a personality or a situation. In sport he was an all-rounder, though his activities in this field had necessarily been curtailed of late. The deep sense of loss felt by his colleagues will also be shared by the many nurses who worked with him. He is survived by his widow and a young son, to whom the sympathy of many friends will be extended.—J. R. M. W.

Medico-Legal

A STILL LONGER GESTATION PERIOD

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Where divorce suits have been founded wholly or chiefly on abnormal length of gestation the Divorce Court has accepted as possible periods of gestation 346 days in 1947 and 349 days in 1948.[1] Mr. Commissioner Blanco White, recently retrying a petition previously heard at Chester in December, 1947, would not reject 360 days.[2] A leading aircraftman serving in Germany had home leave from Aug. 7 to 17, 1945, and was demobilized on Feb. 9, 1946. Between those dates he had no access to his wife, but on Aug. 13, 1946, she bore a child which weighed 8¼ lb. and was apparently normal in every way. This meant a gestation period of either 186 days or 360 days. The wife, so far as the evidence showed, was a respectable and hardworking woman with a small child who lived with her parents. She worked as an assistant linesman on the railway. No allegation of misconduct was made against her. In November and December, 1945, about nine months before the birth, she wrote to her mother-in-law and husband as if with a clear conscience, and when it took place she notified him by telegram and by letter.

The Commissioner was satisfied on the medical evidence that the child could not have been conceived as late as 186 days before the birth, but on the question whether the 360 days' gestation was possible he had to ask himself whether the extra 14 days over the period of 346 days previously accepted by the courts was such as to tip the balance between a reasonable and a fantastic doubt, for adultery has to be proved beyond reasonable doubt. He did not think it right to condemn this respectable woman, who had sworn that she had not committed misconduct, on speculation alone. He could not say, on the court's judicial knowledge of natural laws, that 360 days was an impossible period, and so was not satisfied beyond reasonable doubt that adultery had been committed.

An appeal has now been entered in this case.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examination indicated:

FINAL M.B.—*Part II (Principles and Practice of Physic, Pathology, and Pharmacology)*: J. Armstrong, G. K. Barker, A. Bates, P. E. Bodkin, I. I. Bornstein, E. C. A. Bott, J. F. Boyle, B. I. Brown, P. Bryan-Brown, D. Bulmer, J. F. C. Callow, N. I. Cardno, C. C. Clapham, E. A. Cooper, P. B. Corston, G. A. Court, P. J. Crossland-Taylor, W. G. Dawson, R. D. Eagland, J. G. Elliott, M. A. Epstein, R. W. Fairhead, E. H. R. Ford, P. R. Freeman, A. Gol, D. Gough, G. A. Gresham, B. M. Grimmett, E. C. B. Hall Craggs, J. R. Harris, E. H. Hemsted, R. N. T. Higgins, B. J. Hockey, L. B. Hunt, L. C. Hurst, I. P. James, E. W. P. Jones, M. J. Kehoe, D. S. Kerr, H. P. Kilner, A. J. Lane, D. G. A. Leggett, D. W. L. Leslie, H. P. Lottenberg, J. Lynfield, J. P. Lythgoe, C. McCance, I. R. McWhinney, T. C. K. Marr, J. D. Marsh, E. Monkhouse, W. P. L. Morrison, J. H. Neame, H. R. Odlum, B. W. Peckett, P. T. Perkins, S. T. H. H. Pilbeam, K. N. J. Pocock, A. Polak, H. T. Pym, J. H. Rack, J. M. Roberts, C. A. Rogerson, J. B. Self, V. H. Smith, J. F. Soothill, L. R. Spencer, J. Stevens, T. E. Stockley, R. A. Struthers, T. J. Sullivan, M. K. Sykes, D. G. Thompson, P. W. Thompson, E. Veldhuyzen, D. P. Wagstaff, C. B. Walker, I. S. Waller, S. A. Wartski, J. F. Watkins, R. G. Watkinson, E. J. Watson-Williams, D. D Webb, E. K. Westlake, J. L. Whitby, B. F. Whitehead, M. Wilkinson.

UNIVERSITY OF ST ANDREWS

The following candidates have been approved at the examinations indicated:

M.D.—Elizabeth M. Ford, D. Myles, D. Thomson.

M.B., Ch.B.—W. G. F. Adams, O. R. Akinsheie, Anne Astley, T. S. Beveridge, S. C. Cameron, R. E. Candlin, P. G. Cannon, Jean E. H. Charlton, Elizabeth M. Chester, J. J. Christ, Denys P. L. Cooper, J. A. Doig, D. W. Emuchay, Denys V. I. Fairweather, Eileen R. Forrest, J. L. Galloway, D. G. Garrow, C. W. Grant, P. W. Grant, Sheila C. Grant, J. D. Green, W. Guthrie, J. B. W. Halley, F. T. Hardy, Margaret M. A. Harley, W. A. Henderson, P. M. Joubert, Margaret M. Kennedy, G Kerr, A. S. Liddell, A. S. Lindsay, Doreen S. Lowson, Anthea L. MacBean, Mary E. McGavin, J. A. McGregor, A. D. McInness, A. M. McLeod, Margaret G. Macnaughton, R. A. Main, Pamela A. Mais, Muriel I. K. Nicoll, Isabella G. R. Nimmo, Joan North, Margaret Oliver, Evelyn J. Paterson, Joan E. Perry, I. R. Purdom, I. H. Redhead, A. W. Robertson, Monica V. Robinson, M. Rosen, J. N. Rushforth, A. Saddler, J. Simpson, Isobel M. Smith, A. W. Sumner, G. Williams, Janina Zaborowska.

UNIVERSITY OF LONDON

The following members of the medical profession have been appointed representatives of the University on the governing bodies of the institutions indicated in parentheses: Professor S. J. Cowell

the amendment would be fulfilled if a local authority provided one apparatus. What Mr. Thorneycroft wanted was a stunt and not analgesia.

It was for the clinician to decide what it was best to give the mother and for the Minister to put into the hands of the midwife or the doctor the full range of clinical services which might be necessary. It was not the duty of laymen like Mr. Thorneycroft to say what should be clinically applied in a given set of circumstances. There were other ways of inducing painless birth which were not analgesia. Why did not members of the Opposition move an amendment to provide that streptomycin should be given in all cases of tuberculous meningitis? They could go through the whole range of clinical medicine and insist on each case being mentioned in a Bill. Each piece of clinical practice was a part of the general Health Service. It was the duty of the Minister to put at the disposal of the medical profession the full range of medical apparatus and then to leave the medical profession to apply it in the light of changing experience. In six months or a year this practice might be entirely dated and they would have an Act of Parliament insisting on the administration of an out-dated practice. If Mr. Thorneycroft was better acquainted with the subject he would know that some obstetricians and gynaecologists objected to this form of birth. In this field Parliament must give proper attention to the welfare of the Service as a whole and the health of the patients in particular. It would be sheer idleness to accept the amendment, because the words would mean nothing. Parliament ought not to single out any special form of treatment. It had done so under the principal Act with regard to dental priorities and Members could see what had happened.

Dr. GUEST pointed out that the new Clause included a duty on the local health authorities to secure that the midwives whose services were provided were enabled to render "all services reasonably necessary for the appropriate care" of the women they attended. Surely that provision included analgesia and everything else.

Mr. BEVAN agreed that these words covered the whole range of services which at any moment might be regarded as clinically necessary—not only analgesia but all services.

The Committee then divided and Mrs. Manning's amendment was rejected by 16 votes to 15. Mr. Bing's clause as originally proposed was then added to the Bill.

On the Schedule covering minor amendments of the Acts of 1946 and 1947 Mr. BEVAN moved to insert words to enable the Exchequer grant to be paid on the money which local health authorities had to find to make good the annual deficit of the Central Midwives Board. The Committee agreed to the amendment.

An amendment by Dr. SEGAL to add representatives of ophthalmic and dispensing opticians to the local representative committee was withdrawn when Mr. Bevan agreed in principle to accept it at the report stage.

Drugs for Private Patients

Mr. RICHARD LAW moved to insert words to enable patients who were treated by private practitioners and not under the National Health Service to receive the advantages of the Act so far as pharmaceutical services were concerned. There was a very strong feeling among private patients that they were being unfairly treated.

Consideration of this amendment was adjourned until the Committee resumed for a fourth sitting.

When the Committee resumed on July 6 Mr. BEVAN replied to Mr. Law, whose amendment proposed that a doctor, who treated a private patient could prescribe drugs, medicines, and appliances, which would be provided under the National Health Service. He said that if this were allowed there would be no effective check on expenditure. It was a mistake to say that the Ministry could make regulations to provide for a doctor who was outside the Service being brought inside for disciplinary purposes in this respect. The patients of private doctors were not denied the services provided under the Act: they denied themselves. Probably less than 4% of the population still chose to have private doctors. A large number of doctors in the Service had private patients as well. He saw no reason why they should not have, if they wished to maintain the relationship of private doctor and private patient which had formerly existed, but he saw no reason why Parliament should pump out public money to support the proposition moved by Mr. Law.

The National Health Service (Amendment) Bill afforded unlimited scope for the Opposition to put down amendments to the National Health Service Act, yet the only substantial amendment proposed was this one which added to the expenditure without adding to the Service. A doctor wishing to retain a private patient might be induced to prescribe expensive drugs because the more he satisfied that patient that he was prescribing astronomically the more inclined the patient would be to keep him as a private doctor. Until the Service had stabilized itself Parliament ought not to do anything that would bring about a return to the old situation.

Sir HUGH LUCAS-TOOTH asked Mr. Bevan whether he would accept an amendment which would enable doctors who were in the Service to prescribe for their private patients.

Mr. BEVAN said the fact that a doctor treated a person privately put both of them outside the Service in respect of that treatment.

Sir HUGH LUCAS-TOOTH pointed out that a doctor could prescribe for a visiting patient or for a foreigner.

Mr. BEVAN said the Opposition could have put down an amendment to deal with the problem and exclude foreigners, but all it wished to do was to create bitterness and prejudice without facing the problem. If visitors to this country fell sick they took advantage, as a general rule, of the hospital system, but that was no reason why the Committee should make a general breach in the system.

Sir HUGH LUCAS-TOOTH said that a person could go to a doctor as a private patient and at the same time be placed on the list of some other doctor under the scheme and take advantage of that fact to obtain medicines recommended for him by his private doctor.

Dr. HADEN GUEST said that was not the way that medical practice worked. If it took place it would be regarded as a very serious matter by both doctors. The majority of doctors in the Service were men of the highest integrity. Some forms of treatment were very expensive. It might be necessary to prescribe for patients gland extracts at a cost of £100 per week. To suggest that such treatment should be outside the control of the National Health Service was fantastic. Doctors would resent having to send in two kinds of accounts and would prefer to deal with the matter from a National Health Service point of view. From the doctor's point of view the advantage of the Service was that it got rid of commercialism.

Colonel STODDART-SCOTT drew a comparison between a British subject who paid his taxes and his contributions to the Health Service but could not get that service, while a foreigner was able to get any treatment under the Health Service without being on the list of any doctor.

Dr. SEGAL hoped that Mr. Bevan would set his face against the amendment. He believed that the present glut of overprescribing was a relic of the bad old days. The tendency would diminish as the Service developed. He did not see how Mr. Bevan could make a concession which would add to the opportunities for overprescribing.

Mr. LAW said Mr. Bevan had been unreasonable in arguing that the change proposed was not administratively possible, and unreasonable in arguing that it was a dodge to endow private practitioners with public funds.

Mr. BEVAN said that if a citizen contributed to the upkeep of a park which he never entered he suffered no injustice, because the park was not withheld from him. It was not true that the Government was withholding from a British private citizen what it was giving to a foreigner. Old age pensioners and also wives and children did not pay the contribution and were still entitled to the medical service. If he made the concession which had been asked for, the 4% of population outside the Service would grow very rapidly.

Mr. LAW's proposed amendment to the schedule was then rejected by 20 to 7.

An amendment by Mr. HOWARD to provide for compensation for "loss of remunerative time" by individuals attending hospital management committees or other bodies in place of

the provision in the Bill for compensation for "any loss of earnings" was withdrawn after Mr. BEVAN had given an assurance that the phrase used in the Bill involved no narrowing of the provision.

Election of Chairmen

Colonel STODDART-SCOTT moved an amendment the purpose of which was to provide that the Minister, having nominated every member of every regional hospital board and every member of every board of governors of teaching hospitals, should permit them to elect their own chairmen from among the people he had appointed. The amendment also asked that management committees should be allowed to choose their own chairmen.

Mr. BING said that the power which the Minister possessed enabled him to make appointments of a semi-political nature which it would be difficult for the regional boards themselves to make.

Mr. BEVAN remarked that of all his tasks in connexion with the National Health Service the appointment of boards of governors and their chairmen and of regional hospital boards and their chairmen had been one of the most difficult. He did not seem to have been able to please anyone, but he was consoled by the fact that the regional boards and the boards of governors were settling down quite happily to their tasks. Nothing could be more undemocratic than to permit a body of nominated persons to elect a chairman and thereby to stop the House of Commons from criticizing the Minister for the administration of these boards. The Executive Council was not an agent of the Minister but a statutory and contractual body, and therefore it was proper for it to elect its own chairman.

The amendment was withdrawn.

Mr. BEVAN moved an amendment authorizing him to pay certain expenses to members of subcommittees of the Executive Council. The Committee agreed to this amendment and to further drafting amendments, and the Committee Stage ended.

The Lock Hospital

Sir HUGH LUCAS-TOOTH asked Mr. Bevan on July 7 whether he had considered the proposal of the Regional Hospital Board that the London Lock Hospital should cease to be used as a hospital for the treatment of venereal diseases: and whether such action had received his approval or sanction.

Mr. BEVAN said this proposal had not been before him officially, because the Regional Hospital Board's delegated powers for the planning and development of hospital services in their area did not require them to obtain his approval before they made changes in the use of particular hospitals. If representations were made to him that a hospital ought not to be diverted from or to a particular purpose he would take these representations into account.

Dr. STEPHEN TAYLOR said the Regional Hospital Board had given most careful and sympathetic consideration to the case of the Lock Hospital. Only after the matter had been carefully discussed for a long time did the Board reach this decision.

Mr. BEVAN said it was undesirable that regional boards should be interfered with in their detailed plans.

Analgesia in Childbirth Bill

A Standing Committee of the House of Commons resumed on June 28 consideration of the Analgesia in Childbirth Bill.

Mr. J. J. ROBERTSON said that the Government proposed in committee on the National Health Service (Amendment) Bill to accept in principle new clauses standing in the name of Mr. Bing and Mrs. Mann. Mr. Bevan and Mr. Woodburn took the view that under the National Health Service Act local health authorities could be required to make provision for the supply of apparatus, for transport, and for the training of midwives in the use of analgesia. The domiciliary midwifery service was part of the National Health Service, and the provision of analgesia for women confined at home should not be divorced from other care given by domiciliary midwives to their patients. It would be wrong to single out analgesic apparatus and transport but not to secure that midwives were provided with other equipment and drugs required for the efficient practice of their calling.

Mr. THORNEYCROFT said that those who proposed to make specific provision for analgesia were not the first people to single out something in the National Health Service Acts. The Ministry had placed specific duties on local health authorities. The Government had made it a duty and not the option of the local health authority to arrange for the care of mothers and children under the age of 5. He had no doubt that if the Bill passed there would be a greater use of analgesia. The machines were available and were piled up in the stockrooms of the manufacturers.

Dr. HADEN GUEST said it would be better that action should be taken on an amendment to the National Health Service (Amendment) Bill to confer not only the power to make use of analgesia but power to do everything else necessary to make motherhood safe, to diminish maternal mortality, and to diminish the fear of pain. He thought that in future the psychological and physical preparation of a woman for childbirth would be more important than it was now. Safer motherhood depended on a big and elaborate organization. They had had that organization in London for some time and it could be set up in other places.

Mr. THORNEYCROFT said that if the Government was prepared to put a specific duty on local authorities in respect of the supply of drugs, apparatus, and transport he was prepared to drop the Analgesia in Childbirth Bill.

Mr. BLENKINSOP, for the Government, said Ministers wished to make the position clear by accepting words ensuring that the Minister had power to impose a duty on local authorities over the whole range of the services and not merely for analgesia. After further discussion the proposal that Clause 2 stand part of the Bill was defeated by 21 to 13. Subsequent clauses were accepted with minor amendments. The Bill was then reported to the House.

On July 1 the Bill was considered as amended in Standing Committee, and Mr. THORNEYCROFT offered to accept several amendments proposed by Mr. Bing. Discussion of these continued till the time appointed for the rising of the House, and the Bill did not then receive a third reading.

On July 8 the third reading of the Bill was moved and was rejected by 108 to 44.

Beryllium Poisoning.—Mr. JAMES GRIFFITHS said on June 28 that beryllium poisoning had been added to the list of prescribed industrial diseases. He was also considering a recommendation about certain forms of cancer among nickel workers.

Sickness Benefit.—Mr. TOM STEELE stated on July 7 that it was estimated that about 800,000 persons were in receipt of sickness benefit on June 1, 1949. A statistical inquiry into the average duration of sickness in 1949 was being made, but the results would not be available until early next year.

Extravagant Prescriptions.—Mr. PETER FREEMAN on July 7 asked the Minister of Health whether he knew that much larger quantities of medicines were frequently supplied on National Health Service prescriptions than were necessary, and what steps were being taken to prevent such waste of public money. Mr. BEVAN said a doctor whose prescriptions suggested extravagance might have his prescribing investigated by a local professional committee. Before this he would be given the opportunity of explaining his reasons to, and being advised by, one of the Ministry of Health medical officers.

Health Centres.—Mr. BEVAN announced on July 7 that 26 existing clinics were being run as health centres, medical or dental. One important new scheme was under way, and three other proposals were being considered. Meanwhile a special committee of the Central Health Services Council had the whole subject of future development in view.

The Ministry of Health reports that nearly 26,000 new blood donors were enrolled in the first three months of 1949, bringing the number of donors in the National Blood Transfusion Service to approximately 375,000. During the quarter there were 106,766 blood donations—23,000 more than in the comparable period last year. To keep ahead of the steadily increasing demand of hospitals, and to avoid, where possible, calling on the individual donor more often than twice a year, it is estimated that another 200,000 donors will be required.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 25. [No. 25

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1949 (a)	(b)	(c)	(d)	(e)	1948 (Corresponding Week) (a)	(b)	(c)	(d)	(e)

Rate per 1,000 total births (including stillborn)			28					25		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

‖ Includes puerperal fever for England and Wales and Eire.

EPIDEMIOLOGICAL NOTES

Poliomyelitis

Notifications in England and Wales in the week ended July were poliomyelitis 80 (48), polio-encephalitis 1 (4). (Figures f the previous week are shown in parentheses.) Counting polio myelitis and polio-encephalitis together, multiple cases w reported from the following counties: Cheshire 2 (1), Corn wall 9 (3), Devon 4 (3), Essex 3 (5), Gloucester 3 (2), Her ford 3 (1), Kent 2 (2), Lancashire 5 (5), Leicestershire 2 (1), London 6 (6), Middlesex 9 (3), Oxford 4 (2), Somerset 2 (1), Yorkshire East Riding 2 (0), Yorkshire West Riding 9 (4), Carmarthen 2 (0).

The general epidemiological picture is one of a widespread increase, but the only definite groupings of cases so far reported have been in Newhaven (last case reported June 17), Camborne-Redruth U.D. (last reported case July 8), and Camberwell (last reported case July 7). A feature of the outbreaks has been the occurrence of unusual numbers of multiple cases in families. There have been three instances of two cases in one family, in Camberwell in two instances and in Newhaven in one instance. Cases have occurred among children rather than adults.

Many clinicians believe that muscular activity in the early indefinite stages of the disease is harmful, and Ritchie Russell brought forward evidence on this point based on his questioning of 100 patients who had poliomyelitis in 1947 (*Journal*, 1947, 2, 1023). His conclusion was that "complete physical rest in bed from the onset of the pre-paralytic stage greatly reduces the danger of severe paralysis. Severe physical activity at this stage is almost suicidal, while the continuance of even average physical activity is dangerous." This point was mentioned in the Ministry of Health memorandum published in the *Journal* of July 26, 1947 (p. 141), but did not perhaps then receive the emphasis which should now be given to it.

Food Poisoning at a London Hospital

Over a hundred members of the staff and patients at a la London hospital were affected by an outbreak of food poi ing on July 5. *S. typhi murium* has been isolated from a n ber of those attacked. There is little doubt that the vehi infection was "queen of pudding," eaten by some 600 p at lunch on that day. This pudding was made in two First breadcrumbs were mixed with a custard made fro and the yolks of 200 duck eggs, and baked in the o about half an hour. The white of the eggs was then up with sugar and poured on to the top of the spo grilled until the surface was lightly browned.

No members of the kitchen staff had had any susp illness before the outbreak, and it can be assumed that infe originated from the duck eggs. It is possible that parts of the sponge which had been baked in the oven for half hour may not have reached sterilizing temperatures; but it certain that the heat treatment given to the white of the eg was not sufficient to kill the organisms in this part of th pudding.

This outbreak, together with other recent incidents in whic duck eggs have been involved, is a further reminder of the potential danger of consuming duck eggs without adequate he treatment. Furthermore, unless the origin of the egg is know and it is certain that they are not infected with *S. typhi murium* it is dangerous to use duck eggs in the preparation of merin

Discussion of Table

In *England and Wales* there was a decrease in the not tions of measles 2,289, acute pneumonia 92, and whoo cough 72. The only increase was in the incidence of s fever 207.

The largest declines in the incidence of measles were Lon 295, Warwickshire 254, Yorkshire West Riding 254, Kent Sussex 131, Surrey 122, Middlesex 111, and Northumberl 108.

There were only small changes in the notifications whooping-cough, notably an increase of 31 in Essex and decrease of 55 in Lancashire. An increased incidence of scar

fever was reported throughout the country; notifications increased appreciably in Yorkshire West Riding 42 and Warwickshire 34.

The 73 notifications of diphtheria represented a new low record, which was eight less than the previous lowest return. The chief feature of the returns for diphtheria was the rise in London from 10 to 17, due mainly to an outbreak in Bermondsey with 10 notifications.

A further 28 cases of paratyphoid were notified from the outbreak in Durham (Hebburn U.D. 17; Jarrow M.B. 7). Notifications of dysentery from the outbreak in Lancashire, Liverpool C.B., numbered 32, which was six more than in the preceding week.

In *Scotland* decreases were recorded in the notifications of measles 118, whooping-cough 44, and scarlet fever 21, with a rise of 14 in the incidence of dysentery. This increase in dysentery was due to the experience of Glasgow, where the notifications increased from 18 to 31.

In *Eire* there were falls in the notifications of measles 59, whooping-cough 13, and scarlet fever 6. In contrast to the general trend a rise of 17 in the notifications of measles was reported from Dublin C.B.

In *Northern Ireland* there was an increase of 21 in the notifications of measles. This increase was confined to two counties—Antrim 10 and Armagh 12.

Week Ending July 2

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,031, whooping-cough 2,260, diphtheria 80, measles 6,984, acute pneumonia 376, cerebrospinal fever 23, acute poliomyelitis 80, dysentery 49, paratyphoid 13, and typhoid 4.

Medical News

Twelfth British Congress of Obstetrics and Gynaecology

A dinner was held in the Guildhall on July 8 at the conclusion of the Twelfth British Congress of Obstetrics and Gynaecology. Sir Eardley Holland, president of the Congress, was in the chair, and the guests included the Archbishop of Canterbury, the Lord Mayor, and Lord Webb-Johnson. Sir Arthur Gilliatt, president of the Royal College of Obstetricians and Gynaecologists, in proposing a toast to the Lord Mayor, referred to the powers of the connexions between the City and the Royal Infirmary and the close association of the present Lord Mayor before he was at St. Bartholomew's Hospital. The Lord Mayor replied, and welcomed the visitors from overseas to the City. Dr. J. V. Bonney proposed "The Congress," to which Sir Eardley Holland responded. Mr. Victor Bonney proposed a toast to "The Guests," who, he said, represented over 20 countries. Dr. Claud Gauclère (Paris) and Professor Ebbe Brandstrup (Copenhagen) replied. Professor Hilda Lloyd proposed a toast to Sir Eardley and Lady Holland.

World Federation for Mental Health

At a Press conference held in London on July 7, Dr. J. R. Rees, president of the Federation, spoke of the immediate plans of his organization and the difficulties it was now facing. The consideration, which was in the first year of its existence, was made up of 55 societies representing 33 countries, and more were to be admitted. It enjoyed consultative status to Unesco and accredited to WHO. Dr. Rees said that it was planned later to carry out a world-wide investigation of mental health, but even that on more limited activities their financial difficulties were considerable. The Federation needed £30,000 a year in order to appoint and establish an office in Geneva and arrange meetings of its committees. At present the offices of the Federation were in London, and delegates travelled to the conferences at their own expense. He added that an anonymous donor had recently given £2,500 for three years as the salary of a medical director, and the Macy foundation had made a grant of $45,000. The first congress to be held in Geneva in August would discuss how the Federation could contribute most usefully to the plans of WHO. Dr. Rees hoped that surveys of rural, industrial, and student mental health could be carried out, making use of the existing administrative machinery of WHO. He emphasized that the Federation would not be made up solely of medical men and women, but would include educationists, journalists, and representatives of other professions concerned with mental health and public education.

Royal College of Obstetricians and Gynaecologists

The Honorary Fellowship of the Royal College of Obstetricians and Gynaecologists was conferred on Sir Henry Dale, O.M., F.R.S., and Professor E. J. Heyman, of the Radiumhemmet, Stockholm, at a meeting of the council of the college held on July 5. Professor Hilda Lloyd and Professor Chassar Moir, sponsoring Sir Henry Dale, referred to the effect of his work on ergot and pituitrin on practical obstetrics. Dr. Malcom Donaldson and Miss Martindale introduced Professor Heyman. The president of the college, Sir William Gilliatt, welcomed the new Fellows.

South African Medical and Dental Council Overruled

Recently the Medical and Dental Council of South Africa refused registration to Dr. Grantly Dick Read. This ruling was set aside by the Supreme Court on June 23. According to Mr. Justice de Villiers, " . . . as the Act and the rules now read, in my judgment, Dr. Read has fulfilled all the conditions requisite for registration, and the council had no jurisdiction to refuse him registration on grounds extraneous to the clear provisions of the Act."

Rye Flour

The Ministry of Food states that patients who are allergic to wheat or wheat-flour extracts need no longer produce a medical certificate to obtain supplies of rye flour. They should try to get rye flour from a retailer in the normal way. If they have any difficulty they should seek advice from the local food office.

Commonwealth Fund Fellowships

Appointments to Commonwealth Fund Fellowships in Medicine from September, 1949, are announced as follows: J. C. S. Paterson, M.B., Ch.B., M.R.C.P. (to University of Rochester); G. J. Romanes, Ph.D., M.B., Ch.B. (to University of Columbia); and G. Smith, M.B., Ch.B. (to Johns Hopkins University). Information concerning Fellowships, which are offered by the Commonwealth Fund of New York, may be obtained from the secretary, Commonwealth Fund Fellowships, 35, Portman Square, London, W.1. Appointments are tenable by British graduates in American universities for one year.

Sanderson-Wells Prize

Dr. S. S. B. Gilder, assistant editor of *Abstracts of World Medicine*, has been awarded the Sanderson-Wells (Senior) Prize of the University of London for 1949 for his essay entitled "Symptoms and Signs of Experimentally Induced Vitamin Deficiency in Man." The prize (value £20) is awarded for the best essay on a subject set by the university submitted within one year of the competitor's taking the London degree of M.B., B.S.

Cambridge Medical Graduates' Club

Mr. W. H. C. Romanis presided over a meeting of the Cambridge University Medical Graduates' Club at Pembroke College on July 8, followed by a dinner in the College Hall. Mr. S. C. Roberts, Master of the College, gave an informal speech of welcome. Mr. H. U. Willink, P.C., Master of Magdalen, said that so far as he could judge the quality of the students entering medicine was high, and Sir Lionel Whitby said a few words about the plans for medicine in Cambridge.

Wills

Dr. Lorimer Gifford Nash, of Ashwell, Herts, who left £55,685, left £100 to the Royal Medical Benevolent Fund; Dr. Walter Edward Manby, of Pembroke, left £24,071; Dr. Harold Edward Gibson, of Seaton, Devon, £19,598; and Dr. Septimus Bodger, of Redditch, Worcs, £19,197.

COMING EVENTS

International Congress of Otolaryngology

The Fourth International Congress of Otolaryngology will be held at King's College, Strand, London, W.C., from July 18 to 23, and will be opened by the Duchess of Kent on Monday, July 18, at 11 a.m.

Old People at Home

A conference is being held on July 20 and 21 at the Royal College of Nursing at the request of the Public Health Section to discuss with representatives of national voluntary bodies immediate and economic ways of helping the aged and infirm in their own homes.

Banting Memorial Lecture

Dr. R. D. Lawrence will deliver the Banting Memorial Lecture at King's College Hospital Medical School, Denmark Hill, S.E., on Friday, July 22, at 10.30 a.m. His subject is "Insulin Therapy; Successes and Problems."

British Standards Institution

The annual general meeting of the British Standards Institution will be held on July 27 at 3 p.m. in the council room of the institution (first floor), 24, Victoria Street, London, S.W.1.

Psychotherapy and the Community

A summer school on "The Contribution of Psychotherapy to the Life of the Community in Medicine, in Education, and in Religion" will be held at the Davidson Clinic, 26, Chalmers Street, Edinburgh, on July 28–Aug. 3. The guest lecturers are Dr. S. H. Foulkes and Dr. George H. Day. Information may be obtained from the secretary at the address above.

International Congress of Catholic Doctors

The fourth International Congress of Catholic Doctors will be held in Rome from Sept. 24 to Oct. 1. An Audience with His Holiness will take place on Sept. 29. "Man in the Light of Medical Science" forms the subject for discussion. Doctors wishing to join the English delegation, which will be led by Dr. W. B. Pemberton, should communicate with Dr. W. J. O'Donovan, O.B.E., 130, Harley Street, London, W.1, before July 31.

SOCIETIES AND LECTURES

Saturday

BRITISH ASSOCIATION OF ALLERGISTS.—At Cardiff, July 16, general meeting. *Morning:* At Medical Unit, Cardiff Royal Infirmary, 10 a.m., "*The Treatment of Bronchial Asthma*," by Dr. Leon Unger; 11.15 a.m., "*Prognosis in Asthma*," by Dr. D. McCracken; 12 noon, "*Sino-bronchial Syndrome*," by Dr. P. T. Bray; 12.20 p.m., demonstration of pollen slides. *Afternoon:* At National Museum of Wales, 2.45 p.m., business meeting; 2.30 p.m., "*Pollen and Mould Studies at Cardiff*," by Messrs. H. A. Hyde and D. A. Williams.

Monday

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, Keppel Street, W.C., July 18, 5.30 p.m., "*Normal and Pathological Physiology of the Kidney*," by Dr. D. D. van Slyke (Rockefeller Institute for Medical Research).

Tuesday

INSTITUTE OF UROLOGY.—At St Paul's Hospital, Endell Street, London, W.C., July 19, (1) 11 a.m., "*Collection of Specimens for Laboratory Diagnosis*," by Dr. R. Thomson; (2) 5 p.m., "*Non-gonococcal Urethritis*," by Dr. A. H. Harkness.

Wednesday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., July 20, (1) 11 a.m., "*Skin Diseases of Possible Venereal Origin: Differential Diagnosis of Genital Dermatoses*," by Dr. W. N. Mascall; (2) 5 p.m., "*Fistula, Carcinoma, and Foreign Bodies of the Urethra, and Injuries of the Urethra*," by Mr. C. H. Mills.

Thursday

DREADNOUGHT SEAMEN'S HOSPITAL, Greenwich, London, S.E July 21, 3 p.m., demonstration by Mr. S. Power.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Str London, W.C., July 21, (1) 11 a.m., "*Yaws, Pinta, and Bejel*," Dr. W. N. Mascall; (2) 5 p.m., "*Tumours of the Testicle*," Mr. W. K. Irwin.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At 26, P land Place, London, W., July 21, 7.30 p.m., "*The Mass Contro Malaria with the New Insecticides*," by Dr. A. Gabal (Venezuela). A discussion will follow.

Friday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Str London, W.C., July 22, 5 p.m., "*Injuries and Diseases of Testicle and Epididymis other than Tumour or Tuberculosis*," Mr. Harland Rees.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E July 22, 10.30 a.m., "*Insulin Therapy; Successes and Problem* Banting Memorial Lecture by Dr. R. D. Lawrence.

Saturday

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.— Leicester Royal Infirmary, July 23, 28th annual general meeti Presidential Address by Dr. C. Hamilton Wilkie; "*The Leices V.D. Clinic and the New Health Scheme.*"

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bishop.—On July 1, 1949, at River Park Nursing Home, Leamington Spa, Dr. Mary (née FitzClarke), wife of Dr. J. W. Bishop, a son.

Blair.—On July 2, 1949, at Queen Victoria Nursing Institution, Wolverhampt to Mary, wife of Dr. Eric J. Blair, a son.

Fraser.—On July 8, 1949, in London, to Edith Victoria (née Foyle, M.B.), v of Frederick E. Fraser, M.B., a son.

Harper.—On June 22, 1949, to Barbara, wife of Ernest Harper, F.R.C.S., East Malling, Kent, a daughter.

Millar.—On July 2, 1949, at the London Hospital, to Patric'a, wife of Dr. Bruce Millar, a son.

Thurston.—On June 28, 1949, at St. Mary's Hospital, Paddington, London, \ to Gabrielle (née Denvir), wife of John V. Thurston, M.B., B.S., a son Graham Patrick.

DEATHS

Birks.—On June 25, 1949, at 4, Goldington Road, Bedford, Guy Thorn Birks, M.B., B.Ch., aged 71.

Briscoe.—On July 1, 1949, James Rynd Briscoe, M.B., B.Ch., of Chardstock

Darroch.—On June 19, 1949, at an infirmary, Glasgow, Margaret Baird Spr Darroch, M.B., Ch.B., late of Blackpool.

Finlay.—On July 10, 1949, at Wells Dene, Gloucester, Douglas Edward Finl M.B., B.S., J.P.

Forman.—On June 23, 1949, at a nursing home, Scarborough, Bernard Gil Forman, M.B.E., M.B., J.P., late of The Beeches, Cloughton, aged 75

Green.—On June 27, 1949, at 24, Romsey Road, Eastleigh, Hants, Le Ernest Green, M.R.C.S., L.R.C.P., aged 45.

Henderson.—*On July 1, 1949, at 52, Prestwick Road, Ayr, George Hender* M.B., Ch.B., *formerly of Peckham, aged 73.*

Hood.—On July 1, 1949, at a nursing home, Thomas Hood, C.M.G., M.R.C. L.R.C.P., of Miramar, Pelham Gardens, Folkestone, aged 78.

James.—On June 24, 1949, at 32, Marine Terrace, Aberystwyth, Gwilym Jam M.R.C.S., L.R.C.P.

Johnson.—On June 28, 1949, Arthur Carveth Johnson, M.B., B.Ch., of Bassaleg Road, Newport.

Jones.—On July 6, 1949, Reginald Lewis Jones, L.S.A., Surgeon-Comman R.N., Ret., of Riversdale, Brixton Deveril, Warminster, Wilts.

Lawrence.—On July 5, 1949, Laurie Asher Lawrence, F.R.C.S., of Bels Square, London, N.W., aged 91.

Leebody.—On July 2, 1949, in Hammersmith Hospital, John Galwey Leebo M.B., Ch.B., F.R.C.S.Ed., aged 49.

Lieberman.—On June 25, 1949, Hyman Barnett Lieberman, M.B., Ch F.R.C.S.Ed., 44, The Rope Walk, Nottingham, aged 46.

Macdonald.—On June 30, 1949, at 73, Greenhill, London, N.W., Geo Alexander Macdonald, M.B., Ch.B., 137, Harley Street, London, W.

Mahony.—*Recently, at 189, Drake Street, Rochdale, Martin James Maho* L.R.C.P.&S.Ed., aged 82.

Milne.—*On July 4, 1949, Alastair David Milne, M.R.C.S., L.R.C.P.*

Milroy.—On July 1, 1949, at 26a, Warren Drive, Wallasey, William Cunnin ham Milroy, M.D., J.P.

Morgan.—*On June 9, 1949, at Virginia Water, Surrey, Laurence Sibast Morgan, M.B., Ch.B., aged 67.*

Ross.—On June 30, 1949, at the Stratford-on-Avon Hospital, Henry Ross, M I C.M., aged 87.

Ross.—On July 3, 1949, at Twickenham, Gilbert Matheson Ross, M.B., Ch.

Simpson.—On June 22, 1949, at Meadow Bank, Thursby, Carlisle, Haro Christopher Simpson, L.M.S.S.A., D.P.H.

Smith.—On July 7, 1949, at home, John Charles Smith, M.B., L.D.S.

Spillane.—On June 12, 1949, in a Singapore hospital, David James Patri Spillane, M.R.C.S., L.R.C.P., Lieutenant-Colonel, I.M.S., aged 38.

Swayne.—On June 30, 1949, at 16, Higher Polsham Road, Paignton, Devo Richard Woodward Swayne, O.B.E., M.B., B.S., aged 69.

Tait.—On June 25, 1949, at a nursing home, Edinburgh, Joseph Gillison Ta M.R.C.S., L.R.C.P.

Willan.—On June 24, 1949, at 14, York Avenue, Hove, *George Th* Willan, D.S.O., T.D., M.R.C.S., L.R.C.P., late Colonel R.A.M.C., aged

Wittkowski.—On June 26, 1949, at Hampstead General Hospital, Da Wittkowski, M.D., 24, Aberdare Gardens, London, N.W., aged 81.

Any Questions ?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Pulmonary Tuberculosis and Pregnancy

Q.—*What is the safest, least violent modern method for terminating pregnancy of two months' duration? The case in question is that of a girl aged 17 who has recently come out of a sanatorium, where she has been for three years with bilateral pulmonary tuberculosis. Although the disease seems to be quiescent at the moment, the patient's general condition is not good.*

A.—Although there may be special circumstances which justify it in this case, a decision to terminate pregnancy should be made only with the knowledge that the consensus of modern opinion is that pregnancy and childbirth do not have any significant effect on pulmonary tuberculosis—no matter whether it be active or quiescent. This is the general conclusion reached by C. J. Stewart and F. A. H. Simmonds (*British Medical Journal*, 1947, 2, 726); R. C. Cohen (ibid., 1948, 2, 775); C. J. Barone, J. A. Fino, and L. H. Hetherington (*Amer. J. Obstet. Gynec.*, 1947, 54, 475); L. L. Friedman and J. R. Garber (*Amer. Rev. Tuberc.*, 1947, 54, 275), and was again expressed by speakers at a meeting held in Newcastle-upon-Tyne on March 25, 1949, and reported in this *Journal* (June 11, p. 1047). The whole subject was also discussed at the recent meeting at Harrogate of the Section of Preventive Medicine (July 9, p. 92). It is extremely doubtful whether induction of abortion improves the patient's prospects—at least in those cases where a sanatorium regimen and collapse therapy are available during and after pregnancy.

If it is decided to terminate pregnancy the operation should be carried out at once, if only because it becomes technically more difficult and dangerous as the pregnancy advances beyond eight weeks. Up to this stage dilatation of the cervix and evacuation of the uterus under general anaesthesia is probably the most satisfactory procedure. Anaesthesia provides little in the way of a problem provided a specialist anaesthetist with modern equipment is available. A method of inducing abortion which has achieved some popularity in this country in recent years is the intrauterine injection of an abortifacient paste. It is attractive in that it is simple and does not require an anaesthetic, but it is a method which is by no means free from risk, nor is it certain in its results. It was dealt with in considerable detail in a reply to a question published in this *Journal* (1947, 2, 317).

"Pituitary Obesity"

Q.—*What is the modern treatment of pituitary obesity? Is there any preparation of anterior pituitary available for use in this condition?*

A.—The diagnosis of pituitary obesity implied in this question is usually made in the absence of any detectable gross lesion, and is somewhat hypothetical. Further, the question implies that the adiposity is due to a deficiency of anterior pituitary and can be rectified by replacement therapy with one of its hormones. If the pituitary itself is a primary cause of adiposity, the reverse of this supposition is probably the case, and the poor food intake with consequent wasting of animals subjected to hypophysectomy but whose hypothalamus has not been interfered with is well known. It has recently been shown that pituitary adrenocorticotropic hormone leads to an increased appetite and increased weight, quite apart from water retention. Therapeutically, in the absence of a gross lesion the treatment of pituitary obesity, or hypothalamic-pituitary obesity, or idiopathic obesity, consists of (1) low-calorie diet; (2) diuretics to counteract water retention; (3) such substances as amphetamine sulphate, which reduce appetite by central nervous action.

Lipstick Dermatitis

Q.—*Is anything known about allergy to lipsticks? What is the treatment in the case of a woman aged 33 who has a condition of the lips characterized by constant painless exfoliation, leaving small raw patches which heal, and by a swelling of the lips about two hours after the application of lipstick?*

A.—Lipstick dermatitis may be due to hypersensitiveness to perfume, fatty base, or colouring matter—usually eosin—and this can be determined by patch-test investigation. The great majority of cases are due to hypersensitivity to eosin, and there may be a superadded factor of induced light-sensitiveness, eosin being fluorescent. There are few lipsticks which do not contain eosin, but such should be sought if that substance is shown to be the cause of the dermatitis; inquiry from recognized cosmetic firms is advised. If the dermatitis is due to perfume or base, a change of lipstick would probably be effective. The previous application of a barrier cream, of the kind employed as a protective against industrial irritants to the lips, has been known to permit the use of a lipstick without injury.

Combined Diphtheria-Pertussis Vaccination

Q.—*A baby, now aged 15 months, had a first inoculation of diphtheria-pertussis vaccine when aged 9 to 10 months. What is the risk of sensitization attacks now? Is it safe to carry on as usual? What dosage is recommended for diphtheria and whooping-cough vaccine, singly or combined?*

A.—There is no risk of sensitization in an infant of 15 months given an injection of combined diphtheria and pertussis prophylactic six months previously. A second injection of 1 ml. of the combined vaccine given now will act as an efficient secondary stimulus. The combination of pertussis vaccine and diphtheria toxoid does not interfere with the immunizing potency of either reagent.

Intravenous Iron Therapy

Q.—*Is there a preparation of iron safe for intravenous use? If so, please give dosage and precautions necessary.*

A.—Saccharated iron oxide in 5% dextrose solution may be successfully given intravenously. Davidson and Girdwood described a dramatic response to saccharated oxide of iron given intravenously in a case of refractory iron-deficiency anaemia (*British Medical Journal*, 1948, 1, 733). Nissim recommended the following course:

10 mg. of iron in	1 ml.
25 " "	2·5 ml.
50 " "	5 ml.
100 " "	10 ml.
250 " "	25 ml.
500 " "	50 ml.

Thrombophlebitis, fever, tachycardia, cyanosis, and headache may arise after the larger doses. A detailed description of the intravenous use of an iron–sucrose preparation has just been published by Slack and Wilkinson (*Lancet*, 1949, 1, 11), and this should be consulted, as should Nissim's paper (Ibid., 1947, 2, 49).

Sulphur-containing Sweat

Q.—*A man of 44, in good health except for a long history of constipation, has noticed that his touch turns silver articles black. What is the pathology and what is the treatment of this complaint?*

A.—It is probable that the black discoloration of silver articles is due to the formation of silver sulphide; the sulphur is presumably derived from the patient's sweat. It is known that chronic constipation is occasionally associated with sulphaemoglobinaemia in the condition called "enterogenous cyanosis." Possibly in the present case the prolonged constipation has been combined with excessive formation of hydrogen sulphide in the bowel, sufficient being absorbed to increase the excretion of sulphur compounds in the sweat. It would be interesting to know if spectroscopy shows any evidence of sulphaemoglobinaemia. Whatever the precise cause, the indication is to establish a normal bowel function.

Osteomalacia or Senile Osteoporosis?

Q.—*What is the modern treatment of osteomalacia, and what is the prognosis? A female aged 65 suffers from this disease, most marked in the bodies of the cervical and lumbar vertebrae. This has led to a loss of weight, knock-knees, and disk lesions at the levels of C4-5 and L5-S1. At present she is having a high-protein diet with 180 gr. (12 g.) calcium gluconate and 2,700 units vitamin D daily and suitable physiotherapy. Serum calcium and urine calcium figures are within normal range. The history is approximately of nine months' duration, and there is no evidence of hormone imbalance.*

A.—If the diagnosis of osteomalacia is correct the treatment being given appears to be appropriate and should prove effective. But osteomalacia is uncommon in this country, and unless there are special features to support the diagnosis it seems more probable that the case is one of senile osteoporosis of the spine. True osteomalacia is usually characterized by curvatures of the tibiae and femora, and coxa vara; the shape of the pelvis is altered, the acetabula being displaced medially. These deformities represent the effect of body weight on the softened bones. In senile osteoporosis the main changes are in the vertebral bodies. There is considerable bone atrophy, and the intervertebral disks bulge into the softened spongy tissue of the vertebral bodies, which assume a biconcave appearance. There is a general kyphosis, often pronounced, and in addition there may be marked wedging of individual vertebrae. The underlying cause of senile osteoporosis is unknown, and curative treatment is not available. Nevertheless the wearing of a light but strong spinal support is often a useful palliative.

Letterer–Siwe's Disease

Q.—*I am interested in a child of 19 months who was taken ill in South Africa some months ago with what at first was diagnosed as glandular fever; she has been ailing ever since, with mild pyrexia, and her condition has recently been recognized as Letterer-Siwe's disease. Would you kindly tell me the cause, treatment, and prognosis?*

A.—Letterer–Siwe's disease is a systemic aleukaemic non-lipoid reticulo-endotheliosis occurring sporadically, usually in infants or young children. It is characterized by fever, marked splenomegaly, some hepatomegaly, generalized adenopathy, eczematous, granulomatous, petechial, or haemorrhagic cutaneous lesions, localized tumours with rarefactions in bone, and secondary anaemia with usually a normal white cell count. The cause is unknown, but possibly may be infective. Treatment is uncertain and unsatisfactory, but chemotherapeutic agents, antibiotics, and x-ray irradiation may be tried. The majority of reported cases have been fatal.

Intermittent Claudication

Q.—*What are the prognosis and treatment of intermittent claudication in a man of 50 otherwise in good health? X-ray examination shows some calcification of the leg vessels. Does this finding add to the gravity of the prognosis?*

A.—The word "prognosis" in this question has a certain ambiguity: it may refer to the survival of the patient or to the survival of the patient's lower limbs. In respect of the first, the outlook at this age is not good and expectation of life is undoubtedly reduced. Arterial degeneration is unlikely to be limited to the vessels of the legs, and many patients with this disorder die from coronary thrombosis; this is a danger additional to the threat to life which would be afforded by the onset of gangrene. The prognosis in respect of the legs is also likely to be poor. At such an age the arterial obstruction is usually diffuse and adequate collateral circulation is difficult to attain; the degenerative process advances more rapidly than in a man twenty years older, and consequently the blood supply to the legs will probably become increasingly defective. Calcification in the arteries of the leg indicates that these vessels are degenerate; it does not make the prognosis more grave. The presence of intermittent claudication is already evidence of arterial inadequacy.

Treatment depends somewhat on the site of arterial obstruction: if of a main vessel, efforts to increase collateral circulation by plasma transfusions, intermittent venous occlusion, and sympathectomy are often followed by improvement. When the distal vessels are affected the prognosis is worse and the results of treatment more disappointing. In both types scrupulous care of the feet is essential if gangrene is to be avoided. The precise details of treatment will be found in any of the current textbooks.

Ergotamine Tartrate

Q.—*A patient who for many years has waked in the night with a severe throbbing headache has received complete relief from 1 mg. of ergotamine tartrate taken prophylactically before retiring. Is this patient likely to develop ergotism, and, if so, approximately how long is it safe to go on giving the ergotamine?*

A.—Different people differ greatly in their tolerance to ergotamine tartrate. Usually 1 mg. is well tolerated, but if the drug is being taken every night the patient must be on the look-out for such symptoms as burning or tingling sensations in the legs, toes, or hands. Ergometrine should be tried instead of ergotamine. Ergometrine is equally effective in relieving attacks of migraine in many people, and does not cause ergotism. If this does not work, then dihydroergotamine (DHE-45) might be given in a dose of 2 mg. This drug is considerably less toxic than ergotamine.

NOTES AND COMMENTS

Dyspareunia.—Dr. B. SANDLER (Urmston, Lancs) writes: May I disagree with the reply given under this heading ("Any Questions?" June 4, p. 1017)? In a patient with a psychopathic background, as described, glass dilators should not be used at all—not even on patients with a normal background are they often required. She should be advised to apply oestrone ointment to the introitus, and then perform self-dilatation by the gentle insertion, first of her forefinger, next of two fingers, and finally of two or three fingers and thumb, over a period of a fortnight. The use of her own fingers is less frightening and more completely controllable; whilst the oestrone ointment produces local vasodilatation, which assists in relaxation.

Report on a Cure for Cancer.—Dr. F. WIBAUT, Secretary-Treasurer of the Netherlands Medical Association, writes: An Amsterdam physician, Dr. J. Samuels, advertises at home and abroad that he has found a universal method to cure malignant and benign tumours, diabetes, and multiple sclerosis. The method consists of radiotherapy by means of radiation with short waves of the hypophysis. Dr. Samuels does not judge the result according to the usual clinical and pathological methods, but by observing the supposed changes in the circulating blood. These changes are alleged to be visible through a fold of the skin by means of a spectroscope. The Minister of Social Affairs, who is also responsible for the supervision of public health, has asked the President of the Council for Public Hygiene to examine this matter. The result of this examination has been that not one single case of cure of the diseases mentioned above has been confirmed. Besides that, the method of diagnosis and the therapy must be looked upon as completely worthless.

The result of the examination has been published as "The Report to the Minister," dated January, 1949 (States Printing Office, The Hague. Price 1.27 florins). An abstract of the report has been published by the medical weekly of the Netherlands Medical Association, *Medisch Contact*. Copies of this issue of *Medisch Contact* may be obtained on application to the office of the Netherlands Medical Association, Keizersgracht 327, Amsterdam (C).

SUPPLEMENT TO THE
BRITISH MEDICAL JOURNAL
LONDON SATURDAY JULY 16 1949

MINISTRY'S REPLY TO CONSULTANTS

The following letter has been sent from the Ministry of Health to Sir Lionel Whitby, chairman of the Joint Committee, in reply to the letter sent by him on July 5:

Dear Sir Lionel,

I have your letter of July 5, telling me the matters which your Joint Committee regard as still outstanding, for further discussion. We are ready to discuss these points at any time—but you will not need me to remind you of the urgency of a decision being reached without avoidable delay.

It may accelerate discussion if I set out shortly our view on your points (i), (ii), and (iii) in Paragraph 2 of your letter.

As to (i), we are at one with you in wanting a permanent negotiating machinery, which we think should be established as a medical section of the Whitley machinery already being developed. There have been delays—e.g., in respect of public health medical officers—but we hope we can soon reach agreement on that.

But you also want to add an absolute right to the medical profession, in the event of disagreement in discussion (within a prescribed range of subjects including remuneration), to refer the dispute to arbitration—both parties then to be bound by the arbitrator's decision. Here we certainly diverge from you, but more in the principle involved than in what we conceive as likely actually to happen.

In the amending Bill now before Parliament we have inserted a provision which gives to the medical profession just the same rights of arbitration as are already given to any other profession or trade; and arbitration would be by mutual consent, as it is for everyone else. (So far as there are surviving wartime powers which go beyond this, you too can use them as anyone else.) But you go on to ask for something which no other profession enjoys, and for something which might produce a situation where the arbitration of one or more individuals could override Parliament and the Government itself—even in circumstances where the national interest was clearly in conflict with it. Constitutionally this would be impossible to accept.

It is important to consider what the practical position is likely to be. There will be, say, a proposal from the profession to raise the capitation fee, or something similar. At this stage neither side ought to be thinking about arbitration. Discussion and conciliation should be the first aim—and normally that should bring agreement, we should hope. But suppose it does not, and a deadlock arises. If arbitration is the obvious course (and there are no serious national considerations against it) it will be agreed upon, and obviously the Minister will normally agree to accept its findings, subject always to the overriding authority of Parliament. And the same would apply the other way round. Alternatively, both sides might prefer, on some subjects, to refer for independent advice to an *ad hoc* committee, like the Spens Committees, or to take any other course which both thought best. Arbitration is not always the best machinery. It can sometimes embarrass those who seek it, by its very finality and inflexibility.

But the main point is that—instead of asking the Government to say now, for ever, that they will accept the dictate of an outside tribunal on any unknown subject, at any future time, whatever its effects on the national welfare which the Government exists with Parliament to protect—it is more sensible and practical to say that, as and when any deadlock arises in future discussion, both sides can consider which is the best thing to do, and if arbitration seems best the Minister will certainly agree to it and to be bound by the result, subject only to Parliament. This would, I think, probably lead naturally to leaving out the words "by the Minister of Health" in the model contract, so that it would simply refer to terms of service "determined from time to time."

Now, as to 2 (ii) of your letter, it is difficult to see how your intentions could be written into any statute or contract. It has been agreed that there will be facilities for private as well as public patients in the hospital service. So long as there is the demand for private practice in hospitals, clearly it will be necessary to secure accommodation for it on the lines contemplated in the Act, and not drive all private patients out of the service and into the nursing-homes. But this cannot be reduced to a formula and written in an Act.

As to (iii), this is a matter not within the control of the Minister, and ought not to be imposed as a condition precedent to the signing of a contract.

On your last paragraph, let me say this. We should certainly be willing to meet the Joint Committee again soon, on the above points, if necessary. But you will appreciate the impossibility of a situation in which consultants and specialists are continuing to be advised to postpone entering into contracts, while being assured by us that any solution will be retrospective for them. This is an aspect that we shall be bound sooner or later to review, and we want you to help us to make any such review unnecessary by joining us in speeding the solution.

Yours sincerely,

(Signed) WM. S. DOUGLAS.

Ministry of Health, Whitehall, S.W.1.

The following letter, which was sent by Sir Lionel Whitby to the Ministry on July 5, is reproduced from the Supplement of July 9 (p. 44).

The Joint Committee at its meeting to-day, after considering the views of its constituent bodies, passed the following resolutions:

1. The Joint Committee finds itself unable at present to advise consultants and specialists to enter into permanent contracts on the basis now offered by the Minister.

2. The Joint Committee finds it essential to reopen discussions with the Minister on the following points:

(i) There should be established for consultants and specialists a permanent negotiating machinery, the Minister or the representatives of the profession having the right, in the event of disagreement, within an agreed range of subjects to refer the matter for settlement by arbitration, both parties being bound by the award of the arbitrator.

The agreed range of subjects should include any terms and conditions of service affecting remuneration.

The form of contract should be revised so as to make it clear that the terms and conditions of service offered are those which have been agreed with the profession or determined by arbitration, and not "determined from time to time by the Minister of Health."

(ii) Facilities for private treatment in hospital should be maintained and developed throughout the country for those who desire them.

(iii) Information concerning the remuneration of part-time clinical teachers should be available before the practitioners concerned are called upon to sign permanent contracts.

3. In the meantime the Joint Committee recommends consultants and specialists not to sign permanent contracts until further advice is tendered by the Joint Committee.

The Joint Committee desires an interview in order to discuss these resolutions.

THE CONSULTANTS' "NO"

A special meeting of the Central Consultants and Specialists Committee was held at B.M.A. House, London, on July 5, under the chairmanship of Mr. R. L. Newell, to formulate a recommendation regarding the acceptance or otherwise of the Ministry's terms and conditions of service of hospital medical staff, which, with an explanatory memorandum, were published in the *Journal* of June 11. The chairman said that there were many matters connected with the terms of service which were extremely important; among them was, most prominently, the question of arbitration, also the form of the proffered contract whereby the Ministry was allowed to change its terms, and other points of perhaps a less crucial character.

A summary placed before the committee of the replies received from the regions showed that in very nearly all in England and Wales the opinion appeared to be against acceptance. The representatives of each of the regions then gave some account of the feeling in their areas. Even those areas which had not answered an emphatic "No" had qualified their consent by insisting on certain conditions of acceptance, most prominently the concession of the right to arbitration. In the Scottish regions the position was rather different; while there was still insistence on rectification of the points at issue, the majority—in some cases the large majority—favoured acceptance.

Before the vote was taken there was some discussion on the question of arbitration. The meeting was reminded that under Section 12 of the amending Bill settlement by arbitration could have effect only if both parties agreed, and the Minister would not say in advance that he was necessarily prepared to agree. One of the Minister's objections to acceptance of arbitration was that it was Parliament—not an external independent person (the arbitrator)—who must determine the size of the budget. But this ignored the consideration that Civil Servants up to a certain salary level (£1,200)—admittedly a level below that proposed for consultants—were permitted recourse to arbitration, and in view of the large numbers so involved an arbitration decision might make far more difference to the budget than any arbitration which concerned the medical profession.

After full discussion the committee decided that consultants and specialists should be advised not to sign the proposed contracts unless certain changes were made.

The question of arbitration was immediately put to the meeting, and received unanimous assent. The Scottish representatives, like those of England and Wales, insisted on the right of arbitration as a *sine qua non* of acceptance. Other matters considered were the unilateral nature of the proposed contract, the doubt as to security of tenure, the apparent intention to diminish if not to eliminate private practice, and the questions attending the creation of the grade of senior hospital medical officers; though on this last question it was pointed out that the eventual agreement might be wholly satisfactory or wholly unsatisfactory, and yet this grading, with its unsatisfactory features and its dangers, would remain.

The resolution agreed upon by the committee was as follows:

That this Central Consultants and Specialists Committee recommends the Joint Committee to advise consultants and specialists not to enter into permanent contracts on the basis now offered by the Minister unless and until the following changes are made:

(1) There should be established for consultants and specialists a permanent negotiating machinery, the Minister or the representatives of the profession having the right, in the event of disagreement, within an agreed range of subjects to refer the matter for settlement by arbitration, both parties being bound by the award of the arbitrator.

The agreed range of subjects should include any terms and conditions of service affecting remuneration.

(2) The contract should be an agreement between contracting parties and not subject to unilateral determination or modification by the Minister.

(3) The safeguards for private practice should be greatly strengthened. For example, Clause 5 of the whole-time contract and Clause 2 of the part-time contract should be amended to make it clear that there will be no encroachment on opportunities for private practice.

HOSPITAL EYE SERVICE

THE MINISTER'S VIEW

The Ministry of Health has sent a circular to hospital boards and committees announcing that the Minister disagrees with an opinion expressed by the Ophthalmic Group Committee and published in the *Supplement* of June 4 (p. 304). The committee expressed the view that ophthalmic opticians employed in the hospital service should be appointed on a full-time basis. The circular states that the Minister "feels it necessary to point out" that this does not represent his policy. In the Minister's view optical staff may suitably be employed on a part-time sessional basis (other than the senior ophthalmic optician, who should be a whole-time officer) as well as on a whole-time basis. "Boards and committees should accordingly have regard to the advantages of part-time as well as of whole-time service when making appointments of optical staff in the hospital eye service."

MEDICINE IN EIRE

DANGERS OF STATE INTRUSION

Dr. P. Moran, President of the Medical Association of Eire, said at the annual meeting of the association on July 7 that medical science was a private, personal, and confidential service, and its value and efficiency depended on mutual trust and confidence of patient and doctor. He is reported in the *Irish Times* as saying: "We unreservedly accept the thesis that the best means of achieving and maintaining, or restoring, health should be available to all, but we reject the thesis that this can best be done on mass-production lines under State control." The Health Act of 1947 was on the Statute Book, he added, but the present Minister of Health had given the association a written assurance that he would not make any major decisions implementing the provisions of the Act without consulting them.

Referring to the British Service, he said it had been very far from an unqualified success, and many were forced to the conclusion that the old system was much to be preferred.

HEARD AT HEADQUARTERS

His Own Doctor

Some practitioners have put their own names on their lists of patients, taking the injunction, "Physician, heal thyself," too literally. The Ministry holds that it is not possible to allow a doctor or anyone else to prescribe for himself under the Act. Nevertheless, there are cases in which some indulgence might be claimed. One case which the Association has brought to the notice of the Ministry is that of a doctor in a rural area, with no colleague within reasonable distance, who prescribed insulin for himself. The prescriptions were disallowed, but on the representation of the Association the sympathetic consideration of the Ministry is to be given to the question of refunding the cost in this instance. And, of course, as one member remarked, "If a doctor removes himself from his list he will then be at liberty to charge himself for any service."

Questions Answered

Disagreement Between Principal and Assistant

Q.—*In the event of a disagreement between a principal and an assistant concerning an increase in remuneration and car allowance, is there any authoritative body to whom the assistant may refer his claim as an alternative to terminating his engagement?*

A.—An assistant is usually engaged on mutually agreed terms, which should be embodied in a properly constituted legal agreement. The contract is between principal and assistant, and either should have the right to terminate it after giving due notice if it should prove unsatisfactory. No third party or outside body can intervene, though by mutual consent a disagreement can be referred to arbitration.

Correspondence

The Tail End

SIR,—For some time I have taken a passing interest in the correspondence in your columns concerning the National Health Service, but as one who leads a comparatively secluded life in a hospital laboratory such problems as the capitation fee, mileage fund, central pool, and so on did not affect me directly except in so much as my sympathy was extended to those who were endeavouring to earn an honest living in medicine. The National Health Service, however, has now washed up against the door of my laboratory for the first time, and the tidal refuse which it has deposited there has compelled me to take a livelier interest in the vacillations of such things as regional boards.

I suppose one might describe me as a middle-aged specialist (whatever that is) or consultant (whatever *that* is) in clinical biochemistry, reasonably well qualified both in science and in medicine, and with some considerable experience in both teaching and research. The glorious fifth of July found me in the position of a university lecturer and one of the honorary (unpaid) biochemists to what was once the largest voluntary hospital in the country.

Like the great majority of others I viewed the whole position with a pair of Micawber-like eyes, and carried on expecting that some day something might possibly "turn up." After eight months I discovered the existence of a body known as the "regional hospital board," and wrote them a timorous little letter inquiring whether or not I was employed by the National Health Service. They stated in reply that they did not know, but that they would set the problem before a committee to find out. Further inquiries spaced at monthly intervals evoked no response until the latter half of June, when two long letters arrived. From these letters three solid facts emerged: (1) that the board hadn't the faintest idea what the position of biochemists was, (2) that the whole matter was being handed over to the university, and (3) that as far as the Spens Report was concerned biochemists didn't exist anyway. Two days later the bombshell arrived.

The university authorities informed me that in addition to my university duties my appointment now covered "all duties which you may be required to perform in connexion with the biochemical services of the regional hospital board." Prior to receipt of this information, it could be calculated that my university salary was £570 per annum. This salary was raised to £650 per annum. The only logical conclusion that one can draw is that my biochemical services to the board are valued at £80 per annum.

Practical joking can be excluded; such an august body as a university court does not indulge in that sort of thing. Clerical error can also be ruled out, since the advice note from the accountant confirmed that the last quarter's salary from April to June had been increased by £20.

The possibility has been suggested that 50% of the revised salary may correspond to university work and the other 50% to hospital work. This implies that, for exactly the same amount of university work, the salary has been reduced from £570 to £325 per annum for no apparent reason. It would also imply that the university is being used to bolster up the Socialist Health Service financially by cutting lecturers' salaries in half. Further suggestions are that the salary will increase annually and that it represents only part-time employment, but the official letter gives no clue to the amount of time ("number of sessions" is, I understand, the modern jargon) that one is expected to devote to one's work; but it seems unlikely that the board would allow me to start up in general practice as well.

One is therefore forced back to the conclusion that the clinical biochemist is rated at £80 per annum. It is interesting to compare this remuneration with that enjoyed by other hospital employees. Omitting the higher-paid ranks, the tail end of the financial scale appears to be as follows:

Porter	£260 p.a.
Female cook	£226 p.a.
Kitchen maid	£195–£211 p.a.
Cleaner	£195 p.a.
Biochemist	£80 p.a.

I can discover no one lower down the scale than the biochemist, if we exclude the ward cat, who has so far avoided nationalization and has been allowed to continue his mousing activities in a purely honorary capacity.

Parenthetically, it is interesting, as indicative of modern methods, that one is not "offered" such an appointment. The correspondence states that "the university court has arrived at the decision that your salary *will be* . . . and that the salary is an inclusive one. . . ." Apparently a university lecturer is *ipso facto* a servant of the Ministry of Health, however much he may be opposed to State medicine.

There is, however, good in everything, and even when the biochemist finds that the bottom has fallen out of the blood-urea market he can still find consolation in appreciating the ridiculous side of it all. More detailed inspection reveals that the revised salary has been paid for only one of the four quarters which have elapsed since the glorious fifth. Deducting income tax, I discover that I have pocketed to date £11 plus a few odd shillings as the financial reward for a year of hospital work under the new Socialist health racket.

Heaven and heredity have combined to endow me with a good sense of humour, and I freely admit that the joke is on me. I have been led up, around, and down the garden by a charming gentleman who regards me as "worse than vermin" and who has given me just sufficient salary to buy enough D.D.T. to poison myself. I must give full marks to the little Welshman who can treat a Scotsman (and an Aberdonian at that, by thunder!) in this fashion and get away with it.—I am, etc.,

Edinburgh. E. B. HENDRY.

Grading of Hospital Staffs

SIR,—I am wondering if it is worth while intervening at this late stage in the unhappy situation in which we find ourselves. It appears to me that the injustices and inequalities, everywhere apparent, of the policy of grading individuals would have been avoided by grading the posts at hospitals; in other words, by fixing the medical establishment, which could be altered later as necessity arose.

Hospital A may have two specialists in a given department with approximately equal claim to consultant status, while Hospital B, in the same region, may be *doing the same work* with a medical officer having neither the background nor degrees considered necessary for the grade of specialist; by fixing the establishment at one consultant per specialty in either hospital and deciding by negotiation among themselves, or by advertisement of the post and appointment in the usual manner, the matter should be settled to the satisfaction of everybody. It is at least in accordance with democratic practice. The acting specialist at Hospital B becomes a senior hospital officer, but this should not prejudice his rising later to specialist status either by virtue of increased experience (it may be under one of the consultants appointed) or by the acquisition of the appropriate degrees. The same principle should apply in appointing subordinate grades to enable the Minister to ascertain exactly the staffing and remuneration costs at each hospital.

On the vexed question of lay versus medical administration it must be conceded that there are strong arguments in favour of conserving our professional resources by increased use of specially trained laymen who should undertake the general organization and supervision of hospitals under the medical staff and in conformity with the decisions of the various committees and subcommittees of the boards. One hears of instances in which secretaries and administrative officers consistently ignore the decisions of properly constituted committees, placing their own interpretation on the Minister's instructions, without prior reference to them, with disastrous results. Committees—lay, medical, or mixed—have the appropriate remedy in their own hands.

In consequence of the reorientation of effective control there are good reasons for increasing the status and power of the

financially as well, but, again, I would stress that in the past these men did valuable and irreplaceable service. But times and needs have changed and—who knows?—in 20 years the pure consultant surgeon and obstetrician may be replaced by the expert in preventive medicine—and how we will all resent and hate it!—I am, etc.,

Irvine, Ayrshire. RICHARD DE SOLDENHOFF.

Marriage Allowances for Medical Officers

SIR,—Mr. Alexander is reported as having replied to a question by Colonel Stoddart-Scott in the House of Commons concerning the marriage allowances of Service doctors that he did not think these officers were badly off compared with other National Service officers. All comparisons, we know, are odious. This one is also entirely irrelevant, for the following reasons.

As Dr. E. J. Trimmer pointed out (*Supplement*, April 30, p. 259), medical officers are fully trained prior to their engagement. They require little preliminary training at Service expense to be capable of the kind of work required. This is also true of officers employed in other professional branches, but there are few of these serving on a National Service basis at the moment.

The majority of the remaining National Service officers have to be trained by the Service prior to their commissioning. Also these men are six to seven years younger and therefore mostly unmarried; hence the problem of such allowances does not affect them.

I can only conclude that the reason for such shoddy treatment is an attempt to browbeat us into signing on for longer engagements (thus making us eligible for these monetary awards amongst other privileges—e.g., leave entitlement). However, I think most of us are made of sterner stuff and will not submit to such pressure. We shall just do our time and depart with bitterness, which is a pity and unnecessary.

Sir, is there nothing that can be done to remedy such inconsistencies? I regret signing myself in anonymity, but circumstances at the moment require this.—I am, etc.,

FLYING OFFICER.

Ethics of the Profession

SIR,—Mr. Bevan closed his speech in the House of Commons on the N.H.S. Amending Bill with a claim so richly humorous, and incidentally untrue, that it should not be, I think, passed over in silence.

Mr. Bevan, in his short term of office, has destroyed certain ethical standards observed by the medical profession in every civilized country for more than a thousand years. He has, by regulation framed on his sole authority, compelled the doctor in his Service to break the Hippocratic Oath to regard the confidences made to him by patients in his professional capacity as the "holiest of secrets." Mr. Bevan now compels the doctor in his Service, by regulations issued by himself since the passage of the N.H.S. Act, 1946, to divulge these "holiest of secrets" to a number of lay persons; the disclosure required involving a practitioner parting with his records of patients, the ultimate destination of which cannot be foreseen. That breach of age-old tradition which has made the medical profession one of the proudest of the great professional bodies will be peculiar to British medicine, where it has hitherto received the strictest observance. Yet Mr. Bevan had the effrontery to declare in his speech in the Commons that he was bent upon "raising the ethical standards of the profession." Comment is superfluous.—I am, etc.,

House of Commons. E. GRAHAM-LITTLE.

POINTS FROM LETTERS

New School Tie

DR. ALAN MABERLY (London, W.1) writes: Any morning now a consultant may find on his breakfast table, to his consternation or gratification, a notification to the effect that he is a specialist. I suggest that much confusion might be saved his patients, and embarrassment to his colleagues, if the regional boards were to issue an appropriate tie for identification. A blazer might be thought to be savouring of advertisement.

Association Notices

FORMATION OF A MERSEYSIDE BRANCH

The Council has formed a Merseyside Branch comprising the following Divisions of the Lancashire and Cheshire Branch: Birkenhead and Wirral, Chester, Liverpool, St. Helens, Southport, Wallasey, Warrington.

The new Branch comes into existence as from the date of publication of this notice.

CHARLES HILL,
Secretary.

PROPOSED MANCHESTER AND EAST CHESHIRE, AND NORTH LANCASHIRE BRANCHES

Notice is hereby given by the Council to all concerned of a proposal that two new Branches should be formed in place of that part of the Lancashire and Cheshire Branch not covered by the Merseyside Branch—namely:

(1) A "Manchester and East Cheshire Branch," coterminous with the areas of the following Divisions of the Lancashire and Cheshire Branch: Ashton-under-Lyne, Bolton, Bury, Crewe, Hyde, Leigh, Macclesfield and East Cheshire, Manchester, Mid-Cheshire, Oldham, Rochdale, Salford, Stockport, Wigan.

(2) A "North Lancashire Branch," coterminous with the areas of the following Divisions of the Lancashire and Cheshire Branch: Blackburn, Blackpool, Burnley, Furness, Lancaster, Preston.

Any Division or member affected by the proposed changes and objecting thereto should write to the Secretary of the Association by Aug. 13, 1949, stating the objection and the ground therefor.

CHARLES HILL,
Secretary.

TUBERCULOSIS AND DISEASES OF THE CHEST GROUP

The Council has approved the formation of a special group of members of the Association engaged wholly or predominantly in the field of tuberculosis and diseases of the chest. Members so engaged are invited to apply to the Secretary for a form of application for membership of the group.

An inaugural meeting of the group will be held as soon as practicable, due notice being given in the *Supplement* of the *Journal*.

CHARLES HILL,
Secretary.

Diary of Central Meetings

JULY

19	Tues.	Organization Committee, 2 p.m.
19	Tues.	Pharmacopœia Subcommittee, 2 p.m.
21	Thurs.	Ethical Rules Subcommittee, 2 p.m.
26	Tues.	Proprietary Medicines Committee, 2 p.m.
27	Wed.	Committee on the Postgraduate Education of General Practitioners, 2 p.m.
28	Thurs.	General Medical Services Committee, 11 a.m.
28	Thurs.	Committee on Psychiatry and the Law, 2 p.m.

Branch and Division Meetings to be Held

DORSET DIVISION.—At Old Shire Hall, Dorchester, Thursday, July 21, 8 p.m., coloured sound film: "Angina Pectoris." Doctors are invited to bring their wives, and nursing sisters are invited.

MID-CHESHIRE DIVISION.—At General Hospital, Altrincham, Friday, July 15, 8.15 p.m., annual meeting.

SOUTHAMPTON DIVISION.—At Royal South Hants and Southampton Hospital, Wednesday, July 20, 8.30 p.m., general meeting. Dr. S. J. Hadfield (Assistant Secretary, B.M.A.) will speak on the present position.

WORCESTERSHIRE AND HEREFORDSHIRE BRANCH.—At Alton Street Hospital, Ross-on-Wye, Thursday, July 21, 2.30 p.m., annual meeting.

YORKSHIRE BRANCH.—At Rehabilitation Centre, Richmond Park Avenue, off Handsworth Road, Handsworth, Sheffield, 9, Wednesday, July 20, 2.45 p.m., annual meeting. President's address by Dr. D. C. Barron: "Rehabilitation Methods"; followed by short talks on this subject by Dr. J. A. L. Vaughan Jones and Mr. F. Holdsworth.

FIBRO-FATTY TISSUE AND ITS RELATION TO CERTAIN "RHEUMATIC" SYNDROMES*

BY

W. S. C. COPEMAN, M.A., M.D., F.R.C.P.

Physician in Charge, Department of Rheumatic Diseases, West London Hospital; Hunterian Professor, Royal College of Surgeons

the observations I here put forward are correct, we are w in a position to turn over a fresh page so far as our nception of certain of the so-called rheumatic syndromes concerned. I am not able to do much more than write chapter heading for this new page; it seems to me, wever, that this new chapter will be worth writing when equate material is forthcoming.

It is generally agreed that much of the pathology scribed for the chronic rheumatic diseases is speculative her than factual. Biopsy does not seem to confirm the rrent impression that muscle or fibrous tissues are generly the seat of cellular change in non-articular rheumatism, r indeed that inflammation is the underlying pathology. So far as aetiology is concerned, I suggest that bacteriogy has had its day, and that the day of endocrinology d perhaps genetics is dawning. The therapeutic witchnt for focal sepsis is slackening—we need an alternative e of thought.

Pathologically, the contribution I wish to make is simple t, I believe, fairly far-reaching in this field. There is a rd tissue, also of mesodermal origin—namely, fat—which s seldom been considered in this connexion, but which ems to be quite commonly subject to pathological varians which may cause symptoms that are labelled "rheuatic." Fatty tissue is widely distributed and constitutes arly 20% of the body weight. It appears to be functional well as protective, and, this being so, it would be strange its functions were not sometimes disordered. One of ese functions seems to be concerned with water storage e most striking example of this is perhaps seen in the haviour of the camel's hump). It has been established recent years by Bishop and others that human fat may ain water to a pathological degree in certain disorders. would seem to be some derangement of this normal action of water storage which underlies the syndromes cussed here.

Fibrositis

Fibrositis as a clinical entity has for many years past en accepted in this country, although its pathological undations are, as has been mentioned, slender, resting most entirely upon the theories of Gowers (1904), the ually unconfirmed histological studies of Stockman (1920), d the suggestion of Elliott (1944) regarding muscle spasm a cause. Stockman defined fibrositis as "a condition of ronic inflammation of the white fibrous tissue of the cial aponeurosis, sheaths of muscles and nerves, ligants, tendons, periosteum, and subcutaneous tissues, curring in all parts of the body and giving rise to pain. hing, stiffness, and other symptoms, the result of preding general infections or local inflammations or injuries."

It is now generally defined less comprehensively as an idiopathic disorder of the soft tissues chiefly characterized by pain and tenderness, which may be local, widespread, or referred, and is often associated with muscular spasm.

Nature of the Pain in Fibrositis

It was only comparatively recently that Lewis and Kellgren and others pointed out that the pain in fibrositis generally has its origin in certain focal points from which the more general subjective pain complained of by the sufferer is referred according to a segmental plan. This referred pain may seem to be situated at a considerable distance from its real origin. A good example is to be seen in those cases of sciatica not due to a disk mechanism, in which the focal point of pain—the "trigger-point"—may be found in the region of the iliac crest or even in the lumbar region. These trigger-points, which when palpable are generally termed "fibrositic nodules," are definite objective clinical entities in so far that when they are found by the examining finger the patient winces involuntarily. They are not merely tender spots, which are also commonly found, but they are specific points at which real pain is produced, and from which the more general pain can be referred by quite light pressure. The existence of these trigger-points is now well recognized in view of the therapeutic success which often attends their injection with focal analgesics in saline. Palpable nodules which are not tender are not infrequently found, but do not appear to be significant from a clinical point of view.

Classification of Fibrositis

Himsworth, in his 1949 Oliver-Sharpey Lectures, has emphasized the liberation of medical thought which has resulted from the substitution of syndromes for "disease entities" as units of illness. The syndrome has its philosophical basis in a chain of physiological processes, interference with which at any point produces the same impairment of bodily function. He points out that the same syndrome may thus arise from different causes. This conception inspires a much more catholic concept of aetiology, which is no doubt fully applicable to the field of "rheumatism" in all its forms. It must not therefore be assumed that the conclusions put forward here are thought to explain more than a certain proportion of cases. It will also be apparent that an aetiological classification will be unlikely of attainment in this field, where causes are probably multiple.

It would seem that the only objective sign of the disorder lies in these localized trigger-points, which are, moreover, sometimes palpable in the form of nodules; it therefore seems reasonable to attempt to classify idiopathic fibrositis according to the anatomical nature of the nodule where this is known or strongly suspected. Very little biopsy or

*Hunterian Oration delivered at the Royal College of Surgeons of gland on March 25.

other work of this nature has been done as yet, and the accompanying table based upon this objective must be regarded as being very provisional. It seems possible, however, that some form of classification such as that which follows might ultimately prove useful.

Classification of "Fibrositis"

Nature of Pain	Site	Clinical Finding	Morbid Anatomy	Cause
1. Focal ..	Tendon or aponeurosis	Nodule, small and hard	Fibrous	Trauma, rheumatic fever
2. Focal ..	Lumbar or gluteal	Larger nodule	Fibro-fatty	Oedematous changes
3. Focal ..	On muscle belly	Smallish elongated "nodule"	Local spasm of muscle fibres	Irritative focus in neural segment
4. Diffuse ..	Whole muscle group	Muscle tenderness	Unknown	Toxaemia
5. Diffuse ..	Many muscle groups	Spasm	Chronic muscular fatigue	Psychoneurosis
6. Diffuse .. (sometimes local)	Subcutaneous tissues	Panniculitis, tender fat deposits	Abnormal oedematous deep fat	Endocrine

Aetiology of Trigger-points and Nodules

It was observed (Copeman, 1943) that the pain in the back which accompanies most pyrexial illnesses is of the same nature and pattern as in fibrositis. It was shown, moreover, that, although the pain disappears with the cessation of pyrexia, the tender trigger-point will persist in a proportion of cases often for very long periods, unknown to the patient. These trigger-points can be reactivated by a recurrence of pyrexia, even if this is due to a different cause. It is therefore suggested that the tissues in which trigger-points and nodules subsequently occur in the course of fibrositis may sometimes have been "sensitized" earlier in life in the course of an attack of influenza or one of the exanthemata. The nature of the lesion may be a recurrent oedema painfully distending certain fat lobules in the deep subcutaneous tissues. It has also seemed certain that trauma, and probably also the direct action of cold, can be causative of similar lesions or at least precipitate their development in this way. No evidence of the direct causative effect of focal infection has been established.

Fibrositis Due to Oedematous Changes in the Fibro-fatty Tissues in Certain Sites

Method of Investigation

The frequency of the occurrence of "fibrositic" pain of the lower back in otherwise healthy young soldiers first stimulated our interest in this matter. As a first step exact measurements were taken of the site of these trigger-points or nodules in a large number of sufferers and a pain chart (Fig. 1) was plotted. The back of every patient who died in hospital was systematically dissected and special reference was made to these areas. As the result of this, and of many subsequent clinical observations and biopsies, certain conclusions regarding "fibrositis" and similar conditions in this and other regions of the body have been arrived at, many of which are embodied in this paper. The pain chart which evolved as the result of plotting the site of the trigger-points or painful nodules in our series of cases of lumbar fibrositis, as already mentioned, was found to outline the erector spinae muscles, the crest of the iliac bones, and the sacro-iliac joints. It was later found that this chart also corresponded with areas in which residual fat occurred, even in patients dead with the grossest forms of cachexia.

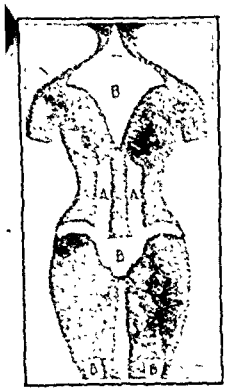

FIG. 1.—Usual sites of fibro-fatty lesions. A, herniation. B, tension pain.

As no evidence of pathological change could be found in fibrous tissue or muscle in biopsy material, we decided to examine the deeper layers of fat which constituted the remaining tissue in the neighbourhood of the trigger-points—notwithstanding the usual assumption that no pathology of interest normally affects this type of tissue. We were lucky in our first case in that we noticed a curious herniation of a large lobule of distended fat through a defect in the deep fascia. In a later biopsy of an easily felt and tender nodule from which widespread pain was being referred we discovered by cautious dissection that the nodule in this case was an oedematous-looking node of fatty tissue lying among superficial fat of the upper buttock, but with a pedicle which could be traced down to the layer of fat lying beneath the deep fascia.

Fatty Structures as a Site for Painful Lesions

In our original paper (Copeman and Ackerman, 1944) we described the areas of fat in which painful "fibrositic" lesions occurred as being in the main "residual," in the sense that lobulated fat remains in these areas even when it disappears from other areas as the result of extreme cachexia. The colour of this residual fat in such cases was often darker or pinker than ordinary fat. In two cases we were able after death to trace the pedicle of a superficial fat hernia down to the paranephric fat mass. These observations suggested to us that the areas of fat liable to be affected, at any rate in the lumbar region, might bear some relation developmentally to the primitive renal fat gland round which, from a comparatively early period of embryonic development, fat congregates in closely lobulated clumps, which in rats (according to Hammar) are also of a darker colour than normal. The well-marked area of residual fat which lines the rim of the ilium may not be covered by this hypothesis, although another primitive fat-organ is described in the outer groin in some textbooks. The largest of these fat-organs is said to be situated between the scapulae—a position which seems to correspond with that of our "dorsal fat-pad."

Normal Anatomical Disposition of Fat

Not much information is to be found on this subject in most anatomical textbooks. Subcutaneous fat exists very generally throughout the body, although its distribution is not uniform. In certain situations it collects more abundantly. Here it forms a considerable layer beneath the reticular layer of the corium, where it is laid down in the subcutaneous areolar tissue—panniculus adiposus. This areolar tissue forms a thin, indistensible fibrous capsule round the large lobules, where the fat is lobulated. T lymphatics serving fat accompany the blood vessels in ve close relation as they enter the lobule. There are numero sensory nerves to the blood vessels, and possibly to oth structures in the lobules, and sympathetic-nerve fibr which run to the fat cells control the function of stora and yielding. Where the skin is thicker and less movab the reticular layer is fixed to the deep fascia by numero stout fibrous bands (retinaculum cutis), the space betwe being filled with firm fat-clusters. This formation normall occurs mostly on the posterior aspects of the trunk an the upper and outer aspects of the limbs.

Pathological Herniation of Fat Lobules

From the brief account which has so far been given will appear that what pass as fibrositic trigger-points ca often be shown to be related topographically in the lumb sacral region with the basic fat pattern. Where these tend points were surgically explored, herniation of distended f lobules through deficiencies in their investing fibrous cove ing was often found. Removal or disruption of the

herniae in such cases provided lasting relief from pain. Histological examination of the material removed has shown in practically every case nothing but normal fat tissue distended with oedematous fluid—suggesting that the cause of this oedema is not inflammatory.

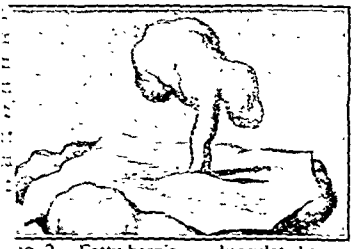

FIG. 2.—Fatty hernia: pedunculated type.

FIG. 3.—Fatty hernia: non-pedunculated type.

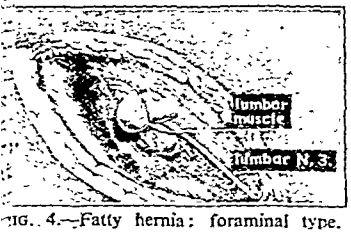

FIG. 4.—Fatty hernia: foraminal type.

In the lumbo-sacral region the fat herniae seen so far have been of three types: (*a*) pedunculated (Fig. 2), (*b*) non-pedunculated (Fig. 3), and (*c*) foraminal (Copeman and Ackerman, 1944) (Fig. 4). The first two are self-explanatory, the herniation occurring from the deeper layer of fat through a flaw in the fascial covering or layer into a more superficial layer. The foraminal herniae occur along the foramina which exist in the deep fascia of the sacro-spinalis muscles, along which pass the lateral branches of the posterior primary divisions of the first, second, and third lumbar nerves together with a small artery and vein.

Twenty-two selected case histories from our series have been published (Copeman and Ackerman 1944, 1947) in which removal of a fat hernia of one of these types resulted in a permanent cure of the pain, and many subsequent unpublished cases have been investigated with similar findings and results. Herz (1945), working in Cleveland, has confirmed this work and has published two further, larger series of successful cases.

Lesions Other than Herniation Occurring in Fat of Normal Distribution

Upper Dorsal Region

The skin is normally six to eight times thicker in this situation than in most parts of the body, and islands of fat may be found actually in the reticular layer of the corium of patients suffering from panniculitis. In the upper back the fibrous projections between the corium and the deep fascia normally form a series of honeycomb-like compartments which are filled with vascular fat. The axes of these "cells" are found to be roughly parallel with the tension (cleavage) lines of Langer. This structure is particularly noticeable in the upper back area, and we have called this diamond-shaped area the "dorsal fat-pad." It is one of the common sites of "fibrositic" pain, and its area corresponds fairly accurately with that of the trapezius muscle which lies beneath it.

When painful nodules are palpable, as is commonly the case in "fibrositis" of this region, they are seldom fibrous in nature. Biopsy will generally disclose the nodule to consist of the fatty contents of one or more of these compartments, swollen and under tension. Tension is shown by the fact that if the incision is made at right angles to the lines of tension in the skin the wound will gape and the lobule will be seen to present above its surface. It is also shown by the *peau d'orange* appearance if the skin and subcutaneous tissues of an affected area are compressed laterally. Negative evidence of this is afforded by the well-attested observation that palpable nodules of this type can be "rubbed away" by means of deep massage; a fact that could not be rationalized if they were formed of solid material such as fibrous tissue. Herniation of these lobules into adjoining compartments has been observed, but is uncommon owing to the density of their walls.

Periarticular Fat-pads

It does not seem to be generally appreciated amongst clinicians that localized collections of fat are to be found normally in association with certain joints, particularly the knees and ankles, and that these may become painful without the joint itself necessarily being affected. When this occurs an irresponsible diagnosis of arthritis is often made as the result of insufficient examination.

(*a*) *The Patellar Fat-pads.*—A normal intracapsular fat-pad is situated between the joint and the patella. This is well recognized by anatomists and surgeons. These infra-patellar pads will often become tender and painful without the joint itself being affected: this is particularly so around the time of the menopause. It is this lesion that commonly gives rise to the sensation of grating on movement, which is sometimes considered to imply that arthritis is present. A fold called the infrapatellar synovial fold extends posteriorly from the apex of each fat-pad to be attached to the femur inside the joint cavity. No doubt in certain cases, if this is also affected, intra-articular function will to some extent be deranged.

(*b*) *The "Popliteal Fat-pad."*—This has not so far as I am aware, been described as a separate entity. None the less, it is present in more than 80% of normal people over

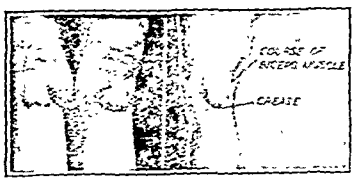

FIG. 5.—The popliteal fat-pads: normal structures which generally enlarge when painful. Often mistaken for bursae.

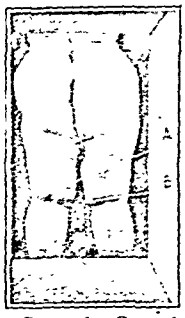

FIG. 6.—General obesity. A, Enlargement of popliteal fat-pads. B, Additional fat-pads at inner aspects of knees. (By courtesy of *Amer. J. med. Sci.*)

40 years of age. When it attracts notice by enlarging and becoming tender it is often wrongly described as a bursal enlargement (Figs. 5 and 6). It is sharply limited at its lower margin by the upper crease of the popliteal skin, and its outer border lies roughly parallel with the course of the semimembranosus muscle. Its upper border, when the pad is large, is delineated by another crease which develops in these circumstances. The inner border lies to the outer aspect of the midline of the popliteal space. This fat-pad lies between the superficial and deep layers of the fascia covering the popliteal space. When large it distends the skin, although the cause of pain and tenderness seems to lie rather in the distension of the fat itself. In these circumstances, however, full flexion of the knee-joint, by compressing the fat-pad, may give rise to pain—and so again to a mistaken diagnosis of arthritis.

The Sacral Fat-pad

This can be observed in about 10% of normal persons (Fig. 7). In structure it is very similar to the dorsal fat-pad. It is rather smaller than the sacrum, but is of the same shape and lies over it. It sometimes enlarges painfully as an isolated phenomenon, but is more often in association with a general condition of panniculitis, either with or without obesity.

FIG. 7.—The sacral fat-pads, present in about 10% of normal subjects.

Two other small fat-pads exist in many normal persons and in all who are obese. I can find no published description of these, however. The first is situated over the dorsal surface of the basal phalanx of the great toe. The so-called "male hairs" described by Wood Jones spring from its surface. It seems to be designed to buffer the strong action between the tendon of extensor hallucis longus and the skin. It is seldom of clinical significance, although its enlargement greatly contributes to the shiny swelling of the skin in this region in cases of acute and subacute gout. The other fat-pads which seem to be of some significance, in so far as they often become swollen and locally painful in obese persons, are situated at the ankle-joint. Medially there is one between the malleolus and the heel, roughly over the flexor retinaculum; whilst on the fibular side one lies over the stem of the inferior extensor retinaculum. A further fat-pad sometimes develops over the adductor tendons of the thigh at their pubic origin. It is rather doubtful, however, whether this can be considered to be of normal occurrence. It always develops in cases of obesity, and may be very painful.

Clinical Effect of Altering Volume and Distribution of Body Fluids

If the views which have been propounded are correct regarding the role of increased fluid tension in certain tissues causing pain, it should prove possible to relieve the pain by reversing this process. An experiment was accordingly planned (Copeman and Pugh, 1945) whereby 22 cases of fibrositis in which we believed that the pain might be of this type were selected. In these patients we induced the state of clinical dehydration; at which point we added electrolyte to the extracellular fluid to increase its osmotic pressure. Since the cell membranes are impermeable to sodium and chloride, intracellular dehydration would result.

The method of achieving this was to restrict the fluid intake of these patients for 36 hours to about 8 oz. (225 ml.). After this they were allowed neither food nor drink for 24 hours, and their fluid output was increased by the administration of ½ oz. (14 ml.) of sodium sulphate at hourly intervals for six doses. The process of dehydration could be followed by noting the daily loss of weight, which varied between 1 and 3.5 kg. This preliminary stage of dehydration was followed by an intravenous injection of 50 ml. of 30% sodium chloride (15 g.) into a vein. Immediately after this injection the patient was allowed to drink 4 oz. (114 ml.) of tea to mitigate thirst. Apart from this no fluid was permitted for four hours, after which no further limitation was imposed and the patient was encouraged to get up and about.

The clinical result of intracellular dehydration in this group was that of the 22 patients submitted 13 were rendered completely free of pain for variable periods. It was thought that this experiment confirmed other evidence about the nature of the mechanism of the pain suffered in the successful cases.

Relationship of Panniculitis with Fibrositis

According to Stockman pain of unknown origin occurring in mesodermal tissue, which he believed (as is indicated by his nomenclature) was always due to inflammation of the white fibrous tissues, is covered by the generic term fibrositis. Pain which has been described above as occurring from the distension in normally situated subcutaneous fat lobules can also therefore conveniently be classified under this heading. Where pain of this type occurs in abnormally deposited fat, however, it will be referred to as panniculitis. The condition was described by Stockman (1911) and also by Telling. It was defined by the former as being fibrosis of the deep subcutaneous tissues, or more specifically as "a chronic inflammation of the areolar tissue of the panniculus adiposus, including the small nerves and blood vessels." Although he recognized the presence of excessive fat locally he considered this to be the result of the inflammation and did not recognize that it had any association with the pain.

Panniculitis is a common condition which is insufficiently recognized as a cause of pain which is not infrequently labelled "psychogenic." Our investigations have shown no single instance histologically of an inflammatory reaction having occurred, and we believe that the pain in this condition originates as the result of oedema, and consequently distension, of lobules of the abnormal fat deposits. Panniculitis can best be considered in relation to those regions of the body in which it is most commonly encountered—namely, the upper dorsal region, the upper and outer aspects of the limbs, around certain joints, especially the knees, elbows, and ankles, and some other sites. Panniculitis is often associated with general obesity. Even in cases showing this association the sites of pain generally remain confined to the regions in which pain is situated in cases not so complicated. This continuing localization of the pain in cases of general obesity may be due to the less lobulated nature of the fat which is laid down elsewhere and also to the fact that in other sites, such as the abdominal wall, no fibrous fascia or capsule is present to limit the distension of the fat if it becomes oedematous. Herniation of fat lobules is common in association with obesity.

Although adiposis dolorosa would seem to differ from the preceding syndrome merely in degree, it does show more generalized areas of pain. The nodular feel of the fat deposits, the fluctuation in the sites of pain, and the histological findings, however, suggest that the underlying cause of the pain may be the same as in the preceding syndromes—namely, a shifting non-inflammatory oedema affecting the pathological fat deposits. In this connexion it is interesting to note in Dercum's (1892) original description that "occasionally very severe paroxysms of pain occurred, and these were coincident with temporary swelling and hardening of the fat masses."

Panniculitis of the Upper Dorsal Region

The "dorsal fat-pad," which has been described as the seat of local lesions in fibrositis, is more generally involved in cases of panniculitis. The tissues are sometimes excessively thickened and the subcutaneous tissues cannot be lifted between the finger and thumb. It is sometimes the only region involved in this process, in which case the condition tends to be concentrated round the base of the cervical spine—the "buffalo hump."

Panniculitis of the Upper and Outer Aspects of the Limbs

Tender nodules not infrequently form along the upper and outer aspects of the thighs, often in association with enlargement of the periarticular fat-pads of the knee, which are discussed below. Pain due to this cause is generally diagnosed as "fibrositis." A few biopsies and dissections have been made in order to study the method of formation of nodules in this site.

The usual situation of these localized collections of fat is in the panniculus adiposus, where certain portions of the areolar tissue seem to become more heavily charged with fat than do others. These portions appear to be more closely lobulated and independent of the average layer of fat at this level, although lying in it, and give the appearance of being small independent "mesenteries" each with its own blood and lymphatic supply. There is also a large potential space between the superficial and deep layers of the fascia which overlies the fascia lata of the thighs, and fat nodules sometimes form also in this space.

In cases in which these collections become painful in this situation it is found that they have become circumscribed by adhesions which seem to prevent lateral extension of the fat mass. The pain is presumably due in such cases to attempted distension of the unyielding fascial walls. The cause of these limiting adhesions is unknown; it may be traumatic, but since their occurrence appears to be related in many cases to the menopause they may result from a drying up of the normal lubricating fluid of the fascia. No detailed investigations have yet been carried out to investigate similar conditions in the region of the upper arm or round the elbow-joints, where panniculitis is also commonly found.

The Knee-joint

An abnormal fat-pad develops over the inner aspect of the knee-joints as a menopausal manifestation and perhaps precursor of ultimate osteoarthritis. It also occurs as a prominent feature of general obesity at any age, and of course in those rare cases known since 1892 as Dercum's disease (adiposis dolorosa). The appearance of these abnormal fat-pads, which may become very large and pendulous, is well known (Fig. 6). They are generally bilateral, although pain or tenderness is often confined to one side only. Posteriorly they cover the lower insertion of the inner group of hamstring muscles, being separated by a definite sulcus near the midline of the popliteal fossa from the normally present (but probably enlarged) popliteal fat-pads described above. Anteriorly they are limited by the internal aspect of the patella, but often appear to blend lower down with the infrapatellar fat-pad. There is no accompanying sensory abnormality of the overlying skin, although it is often the seat of multiple stellate or spider-like collections of thin superficial veins.

Varicose veins and local thromboses are also a common association, as is spontaneous bruising. On palpation distinct lobulation of the contained fat is easily felt, and it can be appreciated that only certain lobules—which feel more tense—are tender. If these be marked it will be found that this localized tense tenderness will affect different lobules on different days. This tenderness appears, therefore, to depend upon a condition of shifting oedema which moves from lobule to lobule. Excision of the painful fat-pad successfully relieves the pain. Microscopical examination shows only oedematous fat of normal structure and with no cellular reaction.

These pads are not to be considered as lipomata; the fat is laid down in the reticular areolar tissue between the corium of the skin and the synovial capsule, into the folds of which lobules will often penetrate and adhere. The arrangement of this areolar tissue does not seem to be as a continuous layer but in discrete sheets which when infiltrated with fat lobules in this way have the appearance each of a separate miniature mesentery. The various collections of lobules are thus in fact discrete clumps, each with its own blood supply and lymphatic system.

These medial fat-pads when they attain a large size can interfere considerably with the free function of the joint, and pain from these is quite often referred to the joint itself subjectively, although carefully objective search will reveal a tense periarticular fat lobule in the pad as its real origin. The differential diagnosis of "arthritis" and its despondent-sounding implications is all too often made in such cases, more particularly if the normally occurring "age-changes" are interpreted as radiological confirmation of this view.

Aetiology

Endocrine

The cause of the non-inflammatory oedema which is found locally to be distending the fat lobules which cause pain in the type of "fibrositis" which has been described, and in panniculitis, is unknown, although it may well be part of a more general process. It may be part of a general condition of dysfunction of fat-water metabolism, as it appears to be in those cases associated with obesity. It is this factor which accounts for those rapid and otherwise inexplicable variations in weight which occur during the dietetic treatment of the obese.

In view of the frequent association of these syndromes with the female menopause (both natural and artificial) it is tempting to suspect that the underlying cause must be endocrine. It seems to be accepted by endocrinologists that excessive secretion of oestrogens in the human will result in water retention, which largely affects the fatty tissues. This is released at a normal period, but if this does not occur the condition may become cumulative. Some reflection of this process is often seen clinically in the cases which have been described. The fault here may lie in the dysfunction of the ovarian glands or, more probably, further back in the pituitary or hypothalamus. The latter probability is strengthened by the fact that men suffer from these syndromes, more particularly the fibrositic one, quite often.

Overactivity of the pituitary and the adrenal cortex is known to be associated with pregnancy and the climacteric, and commonly results in obesity. In most cases, however, no objective evidence of endocrine disorder is to be found, and it may be surmised that the metabolism-regulating centres of the hypothalamus are disordered. This is known to result in water retention, owing to the interference with secretion of the antidiuretic factor of the posterior pituitary lobe. It is said that in these cases administration of chorionic gonadotropin will reduce the subcutaneous fat and release water, and probably the effect of this should be tried in selected cases. It may be presumed that there is no gross pathology present in the majority of the cases which are being discussed, and it seems possible that the lesion may be primarily of genetic determination. The thyroid gland has also been invoked, largely on account of its value in the treatment of certain of these cases; it is thought, however, that as this substance possesses the property of eliminating excessive tissue fluids its benefits probably do not reflect any share in aetiology.

Kling (1947), writing of what he terms "juxta-articular adiposis dolorosa" (probably a condition of panniculitis localized to the joints), states that no high degree of endocrine disturbance was found in his patients, although

B.M.R. estimates were only markedly abnormal in one-third of them. He also failed to find evidence of interstitial inflammation of sensory nerves, but he found evidence of increased tissue tension in these sites and considered it probable that the mere increase of the fat tissue causes pressure on the nerve endings and so gives rise to tenderness and pain. Where enlarged knee fat-pads were only part of a more generalized condition of adiposis dolorosa, these findings were generally found to be applicable to the other joint areas which were affected.

No generalized abnormality has been detected in the majority of our cases of panniculitis; all routine clinical tests, including the B.P. and E.S.R., were normal. Arthritis did not develop in those cases which were successfully treated for the periarticular condition. The condition is not necessarily associated with general obesity, although it may be; and when it is it tends to be more severe and widespread. Adiposis dolorosa, both in its full form and in the periarticular form described by Kling, may constitute only a variation of this entity.

Sodium Balance

Disturbances of water exchange in general betoken dislocation of sodium balance. It can be demonstrated experimentally that cells, including fat cells, swell or contract in a predictable manner in response to variations in sodium concentration in the interstitial fluid, since all cell membranes permit the free passage of water but not of sodium and chloride. The water and salt levels are now believed to be controlled largely by activity of the hormone of the posterior lobe of the pituitary and the influence of the desoxycorticosterone fraction of the adrenal cortex.

Genetic Factors

There may also prove to be a genetic factor involved, since close questioning of 50 unselected female cases of severe panniculitis revealed a history of a similar condition having occurred in the family (mostly in a mother or a mother's sister) in nearly one-half of them. This is a very high proportion, but it does not necessarily point to the disease being a familial one, since all these patients had been subjected to similar endocrine disturbance as represented by the menopause. It is perhaps more probable that it is the body type which is familial, and panniculitis certainly occurs most often in that type which Sheldon (1940) designated the endodermic somatotype.

Cold

It is striking how sudden the first onset of pain may be in some cases, leading occasionally to a wrong diagnosis for this reason alone. It has seemed that in a large number of these cases cold has been the precipitating factor, no doubt merely activating a state already in being. This is understandable in light of the observation of Bazett and his co-workers that a temperature gradient exists between the surface of the body and the deep tissues extending inwards to a depth of 2–3.5 cm. and having a temperature difference ranging from 5 to 15° F. (3–9° C.). The fatty tissues which we believe to be chiefly implicated in the type of fibrositis that has been described and panniculitis lie well within this gradient, and, since the temperature gradient—and to some extent its depth—vary in response to the cooling power of the atmosphere, these tissues must be directly affected by the external environment. These reactions are no doubt responsible for the well-attested phenomenon of weather-sensitivity in these cases.

Treatment

The pain which occurs in the two main syndromes considered in this lecture—namely, a certain type of fibrositis and panniculitis—has been shown to be due in each case to a painful distension of fat lobules within a confined space. Treatment in both will therefore be along similar lines and have the same objectives. Where these syndromes are complicated by the addition of obesity, the factor of weight reduction will also have to be faced.

The results of treatment at the present time are variable, and relapse is common. If the syndrome occurs at the menopause, however, as is not uncommon, and remission can be induced for a sufficient period to cover the completion of this process, prognosis is fairly good. The desiderata of treatment may be epitomized under various headings.

Diet.—Since fat is the site of the painful lesion in these cases weight reduction is always indicated even in patients who do not appear to be overweight. It is seldom that any improvement is noted as the result of other methods unless the body weight is falling. Restriction may be limited to starch-containing foods and to fat. Ordinarily, protein foods need not be limited.

Endocrines.—It has been pointed out that there is clinical evidence that oestrogen tends to cause fluid retention in the tissues, which is released at menstruation, and that in the menopausal patients this condition may become cumulative. Theoretically, androgens might in such cases be the proper remedy, and some recent observations tend to confirm their usefulness. In menopausal cases ordinary endocrine treatment should be tried; in patients who are not menopausal thyroid is none the less sometimes helpful, except in those cases which normally show a rapid pulse rate. In these cases thyroid extract will generally result in palpitations but no reduction in weight. There are no known drugs or hormones which will reduce pituitary activity, although such an objective would seem to be desirable.

Diuresis and Dehydration.—The type of diuresis that is required in these syndromes is that which not only increases the urinary volume but also depletes the body fluids, producing thirst. This is the type called by physiologists "obligatory diuresis." There are several substances which may be employed, and, since there is no contraindication to employing them at the same time, it is reasonable to do so. (*a*) Chemical substances which act by distorting the internal environment, such as urea. This may be given in large doses (20 g.), suspended in a little water or fruit juice after each meal, for long periods. (*b*) Chemical substances which alter the acid-base equilibrium and electrolyte balance, such as ammonium chloride. This is often given to supplement the action of mercurial diuretics, which may also be employed with benefit, and whose effect seems to be to decrease the amount of sodium chloride reabsorbed by the renal tubules. (*c*) A salt-free diet, which is effective in reducing the volume of body fluid where there is an excess. Its effect results from the removal of one of the essential components of this process, whilst restriction of water, the other chief essential, is rendered unnecessary and thirst will thus be relieved.

Physiotherapy.—Firm localized massage is used to disperse the swelling where oedematous fat lobules can be felt and are the cause of pain. It will generally prove very painful at first, and any reaction caused by this process must be allowed to die down before a subsequent treatment of this sort is administered. In time the patient will become less sensitive, and regular treatment will become possible. Previous exposure to radiant heat and infra-red rays will often increase the patient's tolerance to such treatment. Where actual herniation of fat lobules has occurred, but has not become fixed by adhesions, reduction of the herniation by this method may be possible.

Injection.—The object of local injection treatment is to disrupt the swollen fat lobule by hydrostatic pressure and so relieve the painful tension. Mere infiltration with anaesthetic solution will give temporary relief only, except in those infrequent cases in which this procedure has seemed to allow auto-reduction of a hernia, as judged by the subsequent permanent disappearance of both the nodule and the pain. The solution which we have used mostly for this purpose has been procaine 0.5% in saline. Undercutting or "teasing" with the point of the needle afterwards will complete the disruption. In cases of localized panniculitis the affected area may be thoroughly

infiltrated with an oily anaesthetic solution—such as benzyl salicylate—under pressure, with the same object in view. The fibrous compartments separating the fat lobules should afterwards be disrupted with the cutting edge of the wide-bored needle employed, to prevent recurrence.

Surgery.—Surgery has no place in fibrositis in which herniation is not a cause of the pain. Removal of irreducible fat herniae which cannot be disrupted by injection, however, remains the logical procedure, and in well-chosen cases is highly successful. These structures, however, are sometimes surprisingly difficult to locate in a well-covered person and local analgesia is essential, as the patient's subjective impressions are often necessary to ensure that it has been rightly localized. It must not be forgotten that herniations are sometimes multiple. In cases of panniculitis with obesity, persistent pain which cannot be remedied by other means can sometimes be cured surgically by undercutting the painful area. Presumably the sensory nerves responsible are cut in the course of this procedure. In two cases of persistent severe pain situated in an enlarged fat-pad on the medial aspect of the knee-joint the whole pad was excised, with permanent relief of pain, to the satisfaction of the sufferers, who had found no relief from less drastic procedures.

Several papers have been published in America during the last few years confirming the part played by fat herniae in the causation of pain in the lumbar and gluteal regions. The largest series is that of Hertz, of Cleveland. In a personal communication in 1948 he stated that since 1944 his series of such cases had reached a total of 229, 68 of which he had operated upon. At his last follow-up 62 of these had maintained complete relief from pain. Hutcherson, in a paper read before the Association for Surgery of Trauma in July, 1948, reported 42 such cases operated upon, with permanent relief of pain in 40. In England I know of no published series, although I have received accounts of isolated operations of this type which have been successful. Among surgeons who have communicated with me in this way I wish to thank Messrs. L. E. C. Norbury, S. L. Higgs, Rodney Maingot, Harold Edwards, J. C. R. Hindenach, and David Trevor.

Summary

It is thought that an aetiological classification, although desirable in the case of a "disease entity," must remain impracticable in the case of a syndrome. The classical conception of fibrositis is briefly reviewed, and a classification based upon the structure of the nodules found at the source of the pain is tentatively proposed.

Evidence is produced that the fat tissues of the body are subject to pathological variations which cause pain. This pain is generally labelled as "rheumatic" or "fibrositic." When this occurs in the neighbourhood of joints the condition is often wrongly termed arthritic.

It has been shown that several recognizable "rheumatic" syndromes can be the result of an abnormal retention of fluid by fat lobules in certain situations. When this occurs they endeavour to swell, but, being confined by indistensible fibrous tissue, they are unable to do so, and tension pain results. This oedema shows no sign of being inflammatory in nature.

In some such cases a flaw occurs in the fibrous covering, resulting in herniation of the enclosed fat lobule into an adjoining layer. Such herniations may be of three types, which are described.

The origin of this selective swelling is probably endocrine. The direct effect of cold may unmask it.

The syndromes described as being due to this abnormality of fat are: (*a*) "fibrositis," which occurs in any of the several normally occurring fat-pads which are described, and (*b*) panniculitis, which occurs in abnormally deposited fat, mostly in predictable sites. Panniculitis may occur with or without general obesity. In either case the chief sites of pain tend to remain similar. Adiposis dolorosa (Dercum's disease) would appear to be only a quantitative variation of this combination.

Treatment must be directed concurrently along several lines if success is to be achieved. Those discussed include diet, endocrines, diuresis and dehydration, local injections, physiotherapy, and surgery.

The indications for surgery are limited but tend to afford dramatic relief. These are the removal of irreducible fat herniae, and to a smaller extent removal of localized areas of painful tissue in severe cases of panniculitis.

The illustrations are from a film-strip kindly made for me by Mr. E. Wilson in the Photographic Department of the Royal Society of Medicine.

RHEUMATOID ARTHRITIS IN THE YOUNG*

BY

BERNARD SCHLESINGER, M.D., F.R.C.P.

Physician to the Paediatric Department, University College Hospital, and to the Hospital for Sick Children, Great Ormond Street

[WITH PHOTOGRAVURE PLATE]

The aetiology of rheumatoid arthritis still remains unsolved, but fresh light has been cast on the problem by a wider view of the clinical picture. The term "rheumatoid disease" has been wisely suggested (Ellman and Ball, 1948), and realization of the extensive nature of the condition, with less emphasis on the locomotor system, is a great step in the right direction. Arthritis has obviously attracted the most attention, but concentration on this single manifestation has certainly hampered search for the cause. That is why a study of the disorder can most profitably be undertaken in the young, for it is then that disease in general appears in its most acute and unadulterated form.

My remarks will be chiefly confined to certain aspects of Still's disease, which all now agree is no more than an acute form of rheumatoid arthritis in children. Further, I will try to correlate several striking features which have appeared fairly constantly in the group I have been studying with some of the rarer syndromes described by the able physicians of the past.

The study of rheumatoid arthritis, even in children, has to my mind centred too largely on the disease after it has become well established. Investigators have often not the opportunity of witnessing the onset and must rely largely on second-hand accounts from the child's relatives. In this way important developments may be missed.

Acute examples of a disease are also more likely to give information than insidious cases. I have therefore chosen for study from my case notes 20 children all of whom suffered from considerable fever and the usual general acute manifestations first described by Still. In nearly all of them careful clinical observations were made early in the disease, if not from the onset; subsequently the progress of the children was followed for many years, sometimes into adult life.

The account deals particularly with the early stages and general aspects of the disease; following the principles already expressed, arthritis will receive only short consideration.

*Read in opening a discussion in the Section of Rheumatology at the Annual Meeting of the British Medical Association, Harrogate, 1949.

Mode of Onset†

This is more or less abrupt and could often be dated to a day. In most instances there was considerable fever and the disease began with *arthralgia*. At first there was little obviously wrong with the joints until attempts were made to move them, which were painful. Sometimes they were puffy and, though somewhat stiff, movement was not greatly restricted. Later definite *arthritis* set in, but at this early stage it was usually migratory, flitting from joint to joint and lasting only for a few hours (see Chart I). Redness of the surrounding skin has been observed in some instances, and the glistening appearance, swelling, and pain so resembled gout that blood uric acid levels were estimated but were always found to be normal. Sometimes the onset was like that of rheumatic fever, but failure of adequate salicylate therapy soon proved this diagnosis to be wrong.

In a few cases joint manifestations were minimal or entirely absent, and the main clinical features were listlessness, anorexia, adenitis, an unexplained fever, and a rash. The diagnosis then generally inclined towards glandular fever or brucellosis, but this was not supported by laboratory tests.

Adenitis.—This constantly occurred at some period, but with few exceptions could not be counted as one of the earliest features. Once present the enlarged glands persisted throughout the acute phase and disappeared only if the child made a good recovery. When a more chronic form of rheumatoid arthritis developed glandular enlargement continued until the disease became "burnt out."

Splenomegaly.—This was not prominent at the beginning and was found to any degree in only just over one-third of the cases. Later enlargement of the spleen became more obvious.

The Rash.—This appeared in 15 children, usually at the onset, and varied in intensity more or less with the temperature. At a later stage it vanished altogether, and that is no doubt why it has not been greatly stressed in the literature. The rash had a fairly widespread distribution on the limbs, the trunk, and occasionally the face. It was sometimes urticarial at first but without the usual pronounced irritation; soon it became maculo-papular and was often migratory. With the associated adenopathy it is not surprising that cases have been wrongly suspected of being rubella. Rarely the macules fused into a widespread erythema; occasionally petechiae appeared and the capillary fragility was found to be raised.

Fever.—In his original description Still stated that the fever might be continuous or might occur in bouts. Both types were seen in 16 of the 20 patients: usually a prolonged intermittent or a high irregular continuous temperature in the opening stages, giving way to periodic febrile attacks later (see Charts I and II). The periods of pyrexia were not so clearly defined as in Hodgkin's disease or melitensis, or undulant, fever, but careful analysis clearly showed their phasic character, which varied considerably from case to case and from bout to bout (see Charts I–III). In fact, the temperature in some children never remained normal for long; nevertheless the "switchback" appearance of the curves was typical (see Chart IV).

Both joint involvement and the rash tended to lessen or to vanish completely when the temperature dropped. Adenitis and a raised B.S.R., on the other hand, persisted throughout the acute and active stages of the disease. During the bouts of fever the child was very miserable, obviously ill, and in pain. Improvement followed the fall in temperature, but the clinical condition slowly deteriorated with each successive rise. Eventually the febrile attacks ceased and a typical clinical picture of varying degrees of rheumatoid arthritis remained (11 cases). Complete recovery with no obvious residual arthritis was the final result in three (cf. Hench, 1949), death occurred in four from causes which will be discussed later, and in two the acute stage has not yet terminated.

Table incorporating the chief clinical points referred to in the text. Adenitis was an early feature in all cases. Subcutaneous nodules appeared only in Cases 8 and 12 at a later stage. Gold therapy in Case 9 provoked a severe and fatal reaction almost at once.

Blood Picture.—With any prolonged fever anaemia is to be expected, and it was not surprising to find before long a reduction of the red cells to between three and four million per c.mm., with a corresponding drop in the haemoglobin. More significant was the pronounced leucocytosis, almost invariably present at the beginning of the disease (18 out of 20 cases). Counts between 17,000 and 30,000 white cells per c.mm. were commonly registered, with a pronounced polymorphonuclear cytosis in the region of 80 to 90%. Very soon, however, the number of white cells returned to normal and leucocytosis was seldom repeated (see Table and Chart IV).

On rare occasions and at any stage the disease appeared to become too much for the bone marrow. Severe leucopenia then set in. Both neutrophils and lymphocytes might be equally affected, but agranulocytosis has also been observed (Plate, Figs. 1 and 2), and in two cases the final clinical picture and bone-marrow biopsy were indistinguishable from that of *lymphatic leukaemia* in an aleukaemic phase (Cases 1 and 20). Leucopenia developed in four cases—three patients died (Cases 1, 6, and 20), and one recovered rapidly and soon had a normal blood count (Case 15).

Other Clinical Features and Complications

Pericarditis is a well-known manifestation, and occurred in six of the series. It may in fact precede all other manifestations and be mistaken at first for acute rheumatic pericarditis (Chart III). Doubt arises when the illness does not follow the usual course and the myocardium is not found to be greatly involved. Sometimes the physical signs are not very obvious; pericarditis is then masked by the acute febrile disturbance and is observed only at necropsy (Cases 1 and 6).

†The following section should be read in conjunction with the accompanying Table, in which the main features of the 20 cases are summarized.

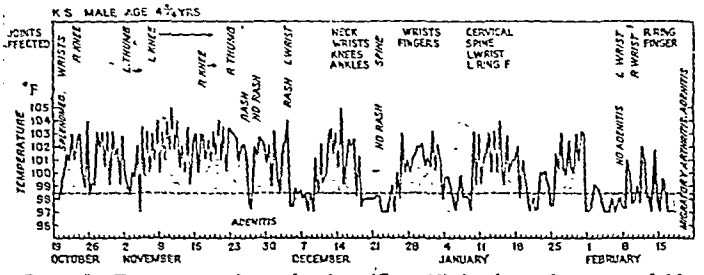

CHART I.—Temperature chart of a boy (Case 10) in the early stages of his disease, showing at first an irregular continuous form of pyrexia which subsequently became phasic in character. The migratory nature of the arthritis is also well demonstrated.

Pleurisy and pneumonitis are commonly associated with the pericarditis, but occasionally they may occur on their own (Cases 13 and 14) (cf. Ellman and Ball, 1948).

Jaundice figured as an occasional complication in Still's riginal account. In the present group it appeared in four ases and the liver became enlarged in nine. In one remark- ble instance (Case 11) the liver and spleen reached well elow the umbilicus, and laboratory tests at the time lemonstrated impaired liver function. After a year's illness ll signs of rheumatoid arthritis vanished; the boy appeared well and active, but was left with an enlarged spleen and *irrhosis* of the liver (see Chart II and Plate, Fig. 3). Amyloid disease has been described (Imrie and Aitkenhead, 1939), but it was never demonstrated during life or after death in the present series.

Only one account of *encephalitis* as a complication could be found in the literature (Spühler, 1941). This was in three adults with Still's type of acute rheumatoid arthritis. In one of my cases (No. 12) convulsions and prolonged coma suddenly developed with pneumonia, pyelonephritis, cardiac failure, and transient hyperpiesia (B.P. 200/120) as additional features (see Chart IV). The boy recovered from all these, but has been permanently aphasic and demented ever since. The aetiology of all this is obscure. Polyarteritis nodosa has lately been much debated in relation to rheumatoid arthritis, and the question naturally arose in this case, but the condition was not confirmed by muscle and vessel biopsy.

Among other early features in the series were excessive sweating, rapid muscular wasting, and generalized bone rarefaction. Later hirsuties, particularly round the labia, was often noticed in quite young girls and is difficult to explain. One other factor should be mentioned: in a few isolated instances the onset of the disease followed within a few hours of some severe trauma or shock, such as a fall down a deep chalk pit, with concussion, or sudden accidental immersion in cold water. Such occurrences may be purely fortuitous and have no bearing on the problem, but they may have some aetiological significance. Similar happenings are well known to anyone who has had wide experience of juvenile rheumatism, and serious relapses have been observed in children with acute rheumatic carditis following fractures, after surgical operation, or subsequent to a long drive in an ambulance (Bland and Duckett Jones, 1935).

Relationship to Other Syndromes

Henry Cohen (1948) in a chapter on "the rarer arthritic syndromes" has picked out one or two groups which seem to be interrelated. Some of them bear a striking resemblance in part of their clinical course to the acute form of rheumatoid disease just described. In his description of *intermittent hydrarthrosis* Garrod (1910) refers particularly to the associated skin rashes, which might be urticarial, erythematous, or haemorrhagic. Although the knee-joints were usually alone affected, others have observed a migratory arthritis. The disorder differs, however, from the disease we are considering in its more benign course and in the greater regularity of its periodic outbursts. In Garrod's cases the condition was mostly superimposed on damaged joints; in mine it was often the precursor of permanent arthritis. It is interesting to find that Garrod also mentions injury as a precipitating cause.

Pyrexia is not a great feature of intermittent hydrarthrosis; when present it coincides with the joint swellings and exhibits a fairly regular periodicity. More severe fever occurred in an allied disorder which Solis Cohen (1913) called "angioneural arthrosis." About 40% of his cases were febrile, and in a number of them the pyrexial attacks had the same phasic character.

Comparable also to a few of the cases in my series was the erythematous or gouty appearance of the joints during the attacks. More or less the same clinical picture was described by Hench and Rosenberg (1944) in a condition they term "palindromic rheumatism," which seems to be a milder form with no effect on the blood sedimentation rate, no fever, a normal blood count, and little tendency to chronic arthritis, but with widespread nodule formation. Palindromic rheumatism has also attracted the attention of Parkes Weber (1946), who finds a common thread running through all these separately described syndromes, including also those of Schlesinger (1899) and Kahlmeter (1939). In many respects their course differs considerably from that of Still's disease in its usual form, but several striking points of resemblance can be found.

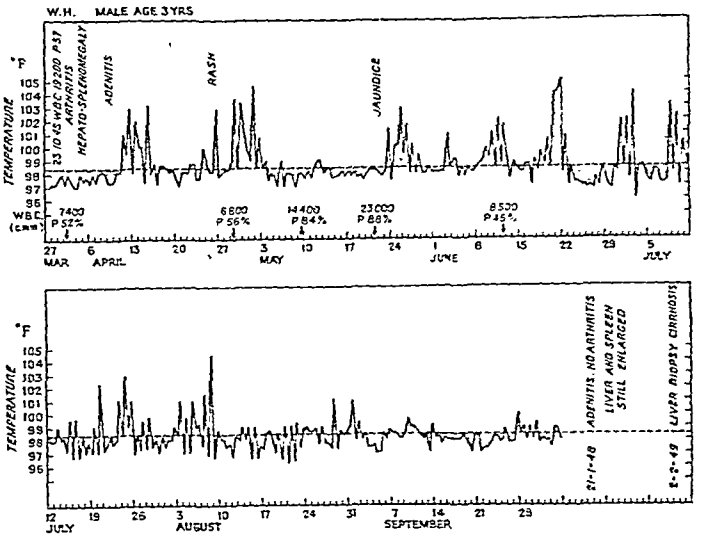

CHART II.—Chart of a boy (Case 11) five months after the onset. Short periodic bursts of pyrexia are shown. Leucocytosis, present at the onset, is no longer evident; the temporary recurrence later was associated with jaundice. There was complete recovery from arthritis, but cirrhosis of the liver developed (see also Plate, Fig. 3).

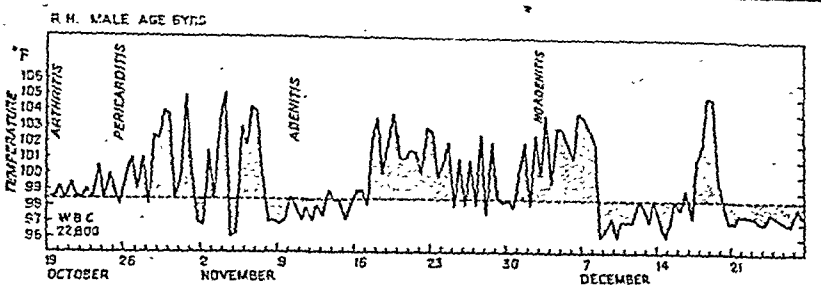

CHART III.—Chart of Case 7 with pericarditis as an early feature. Irregular bouts of fever are again obvious.

Precursor to Leukaemia

The rare termination of Still's disease in lymphatic leukaemia, which I have discussed, raises all kinds of possibilities. Preceding this there may possibly be a stage of undifferentiated leucopenia (panleucopenia), a complication of acute rheumatoid arthritis first described by Felty (1924). In his syndrome the neutrophils were not specially picked out and the low white cell count persisted for many months without the patient being in great distress or the joint affection severe. Felty remarked upon the associated pigmentation and the resemblance of his cases to those described by Banti. The glands and spleen were enlarged but not the liver, although in one case some liver impairment was suspected.

There are also one or two accounts of agranulocytic leucopenia in rheumatoid arthritis, not attributable to any specific form of therapy (Collins, 1937; Blechmann and Carcanagues, 1940). None of these cases proceeded to leukaemia, but this followed in one patient described by Türk (1938).

It seems as if the severer cases of Still's disease are in danger of developing leucopenia. From this the patient can occasionally recover, but the condition is more likely to proceed to agranulocytosis and in rare instances degenerate into leukaemia. Further research by repeated bone-marrow biopsy during the course of the disease is required in order to discover the exact sequence of events.

Discussion

Recently some form of allergy has again been suggested as the basis of the pathological process in rheumatoid arthritis, and in support of this two rare conditions—lupus erythematosus and polyarteritis nodosa—have been repeatedly quoted. Both are thought to be allergic disorders and to bear a certain resemblance to acute rheumatoid disease. This is suggested by the pathology of *lupus erythematosus*, in which the collagen tissue is chiefly affected by fibrinoid changes (Klemperer, 1948; Humphreys, 1948). The clinical features—fever, glandular swelling, arthritis, anaemia, leucopenia, and occasionally pericarditis and diffuse or focal cerebral disease—are also significantly similar to the symptomatology we have been considering. Focal myocarditis, another frequent lesion in lupus erythematosus, might be taken as further evidence of a common pathology, particularly by those who consider rheumatic fever and rheumatoid arthritis to be associated.

The morbid anatomy of *polyarteritis nodosa*, on the other hand, does not seem to bear such a close relationship, but its clinical course is somewhat similar, particularly the arthritis, fever, sweating, prostration, tachycardia, skin eruptions, and occasional involvement of th pericardium (Schlesinger and MacCarthy, 1949)

Glomerular nephritis, which is common i these two rare disorders, is not a feature o Still's disease. The link here is perhaps mor with serum disease produced experimentally i animals and resulting in a number of lesion which are also found in human serum diseas nephritis, polyarteritis nodosa, rheumatic feve and rheumatoid arthritis.

Comparison of Still's disease with thes two rare disorders, whose character ha only recently become clearer, and with syndrome of the past in which an infective factor has alway been in doubt does seem to favour some allergi basis as the underlying cause. Its exact form is still mos obscure. No one has yet discovered the nature of th antigen, explained how it produces a prolonged disease with progessive inflammatory lesions, or discovered what pre disposes certain individuals and allows others to escape Possibly some organism, normally innocuous, may be livin in harmonious symbiosis with its human host and suddenly become pathological when the balance is somehow deranged by stress or trauma. This might explain th occasional effects of shock, to which attention has already been drawn.

The dual role, partly infective and partly sensitizing, tha bacteria can play in the development of disease is wel known. The tubercle bacillus in tuberculosis and th streptococcus in nephritis and in purpura are good examples So far no specific infection has been constantly found t precede the onset of rheumatoid arthritis, but an infectiv factor is strongly suggested by the pronounced polymor phonuclear leucocytosis which was revealed in the early stages of nearly all the cases under review. Leucopenia and agranulocytosis might possibly be the detrimental effect o the bone marrow of repeated allergic reactions.

The changing character of the fever from a more or less continuously high level to an irregular periodicity migh also conceivably be regarded as the successive result of an infective and an allergic process.

Mesenchymal lesions in the skin, lymph nodes, joints heart, lungs, and spleen result from the experimenta

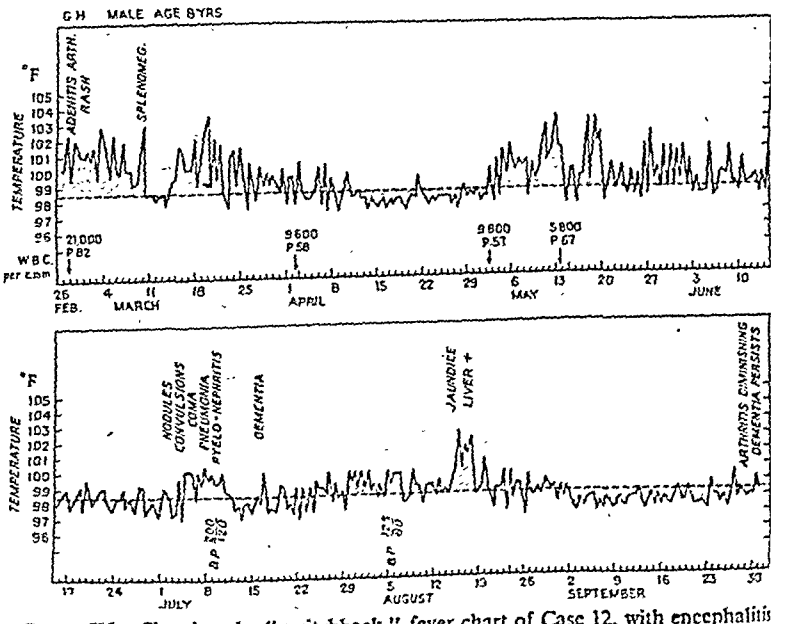

CHART IV.—Showing the "switchback" fever chart of Case 12, with encephalitis and dementia as complications. Initial leucocytosis occurred, but did not persist for long

intravenous injection of soluble antigens (horse serum) into animals, while somatic antigens (whole bacteria) produce their effect mainly in the lungs, liver, and spleen (Ehrich *et al.*, 1949; Gregory and Rich, 1946). Most of these are regions commonly involved in Still's disease, and, as has been shown, the lungs, the heart, and the liver may not escape.

Conclusions

Study of the most acute cases of Still's disease emphasizes the widespread nature of the lesions. Although the majority of cases proceed to progressive arthritis, some patients may recover completely. Characteristic types of pyrexia can be recognized at different stages, and significant effects on the blood picture have also been observed. In rare instances the clinical picture may change from Still's disease to leukaemia. The close resemblance of Still's disease, particularly at the onset, with certain rare syndromes of an allergic nature suggests that rheumatoid arthritis may have a similar aetiological basis. Should this be so, some form of primary bacterial invasion seems to be likely in the course of events.

I am indebted to several of my medical colleagues for allowing me to study their cases, and to Dr. Bodian and Mr. Martin for the histological sections and microphotographs reproduced in the photogravure plate.

The current issue of *Planning* is the three-hundredth in the series which PEP began some 17 years ago. It looks back on the early history of PEP between its foundation in 1931 and the outbreak of war. A brief account of its origin mentions the men who were most concerned with the development of the group. In the early days PEP was given some special grants by the Rockefeller Foundation, but over the period 1933–9, 12 major and two minor reports and more than 150 broadsheets were published on a budget of no more than £56,000 for these seven years. There is a brief description of the *ad hoc* working groups set up by PEP, and an attempt is made to assess its contribution to contemporary knowledge and ideas. The first major report to be prepared by the Civic Division of PEP was that on *The British Social Services*, and this was followed in December, 1937, by the *Report on the British Health Services*. Three groups which did important work during the war were the Social Security Group, the reconstituted Health Group, and the Population Policies Group. The report on *Population Policy in Great Britain*, however, was not published until April, 1948.

PSYCHOGENIC RHEUMATISM

BY

WILLIAM TEGNER, M.R.C.P.
DESMOND O'NEILL, M.D., M.R.C.P., D.P.M.
AND
ANNA KALDEGG, Ph.D., B.A.
(From London and Guy's Hospitals)

In a large hospital to which patients are referred suffering from "rheumatism" considerable diagnostic experience is needed in order to classify the various conditions included in this omnibus term. There is no agreement at present on the scope of the term; it is customarily taken to indicate a group of painful disorders of the locomotor system. It is obvious that a large number of syndromes come under this heading. While the arthritides, neuralgias, and other somatic conditions as a rule present straightforward signs and symptoms, patients are continually encountered whose experiences do not seem to fit in with any recognized syndrome and in whom physical signs are absent or minimal. In such cases one may be tempted to regard the patient as suffering from pain which is primarily of psychogenic rather than organic origin. If this hypothesis is correct, it is plain that rheumatic disorders of this type call for particular care in diagnosis and for treatment more far-reaching than analgesics and physiotherapy.

In recent years there has been a growing disinclination to accept all rheumatic complaints as somatic in origin. Even before the war one of us had coined the term "polyalgia syndrome" to describe the symptoms of which some patients complained. In England, Ellman *et al.* (1942) studied 50 patients with "fibrositis": 23 had no physical signs, although they had been diagnosed as suffering from somatic disease; 25 showed hysterical tendencies. An interpretation of the rheumatic complaint in psychological terms was given by these workers. An important contribution was made by Flind and Barber (1945); many of the subjects investigated by them were found to be suffering from psychiatric rather than organic states. Hench and Boland (1946) gave a full description of psychogenic rheumatism in a paper on the incidence of rheumatic disease in the United States Army; this condition was the third most common diagnosis made in their series of 800 patients.

If psychogenic rheumatism is to be accepted as an entity both by those who diagnose and treat rheumatic disease and by psychiatrists, our concept of it needs clarification and acceptable diagnostic criteria must be established. This demands close collaboration between clinician and psychiatrist: it is the purpose of this paper to show the results of such an endeavour.

Fifteen patients regarded by the clinician as suffering from psychogenic rheumatism were referred for detailed psychiatric examination. In each case the patient was first examined by routine clinical methods. The haemoglobin and sedimentation rate were estimated. The group contained 14 women and one man; the distribution by age was: 15–29, four; 30–39, three; 40–49, four; 50 and over four. The preponderance of women in this group was in accord with the assumption that psychogenic rheumatism in clinical practice is considerably commoner in women. A control group of patients suffering from a painful disorder of which the cause was known was investigated by the same means. This group consisted of subjects of the same age and sex distribution, and broadly of the same social class. The diagnoses were: osteoarthritis

brachial neuralgia (3), fracture of a joint (3), cervical rib (1), periarthritis (1), lesions of an intervertebral disk (2), rheumatoid arthritis (1), alveolar abscess (1). The psychiatric examination was conducted along three main lines—clinical interview, psychometric examination by two projective methods (Rorschach test and Thematic Apperception test—T.A.T.), and appraisal of information given by a relative, employer, or friend.

Results

A. Form of Rheumatic Complaint

Expression of Complaint.—Brief and consistent terms ("sharp," "sore," "aching"): controls, 10; patients, 3. Compound or unusual terms ("twisting," "heaviness," "burning," "stinging and stabbing," "shooting and numbness," "terrible," "hard to describe"): controls, 5; patients, 12. The patients often seemed to be trying to put into words an indescribable sensation. The impression to the observer is frequently that of a mystical or ecstatic experience, with an undercurrent of satisfaction, which recalls Helene Deutsch's (1947) elaboration of masochism as a primary feminine trait. Terms may be used which convey the description of a mental state rather than of a physical stimulus—e.g., "irritation." The psychological precipitants are at times stated quite plainly—e.g., "boredom causes irritation."

Site of Discomfort.—Localized: controls, 11; patients, 3. Widespread: controls, 4; patients, 12. In the majority of the control group discomfort was confined to the area of the lesion or to an area related to it. The distribution of discomfort in the test group was commonly very extensive—e.g., neck, spine, knees, shoulders, calves, hands. The phrase "pain all over" was employed by several patients.

Factors Influencing Severity of Discomfort.—In the controls the most common aggravating factor was touch or movement of the affected part: 11 cases. Among the patients the following were mentioned: work, 4; relaxation, 4; mood, 2; noise, 1; heat or cold, 2; doubtful, 2. Relief of distress in the control group followed rest in 10 cases and treatment in four. Of the patients, seven did not admit relief with any activity or form of treatment; in the remainder some relief occurred with rest or exercise, a hot bath, or quiet. Analgesic drugs produced improvement in six out of seven control subjects in which they were tried; out of eight patients, none noticed any effect from these drugs. Two control subjects considered that the complaint was influenced by their state of feeling, as compared with six patients. Variations in the severity of discomfort throughout the 24 hours, or from day to day, showed no great differences between the groups. The effect of climatic conditions—cold and damp—was similar in both groups. Degrees of disability from slight to total were noted in six control subjects; only one patient suffered any disability, and this was slight.

Associated Symptoms.—Depression, tension, irritability, poor sleep, or phobias were present in 14 of the patients and in five of the controls. In two of the latter the nervous symptoms were considered to be secondary to the somatic disorder.

B. Circumstances of Onset

Two of the controls and 13 patients became aware of the onset of the disorder in circumstances associated with emotional tension. In the remaining 13 controls the onset of illness appeared to be fortuitous. In the majority of the test group the rheumatic condition could be shown to have a comprehensible meaning in relation to the patient and her life situation.

C. Psychiatric Status

Clinical Examination.—In 10 of the control group no significant psychiatric abnormality was found. In the other five the physical condition was accompanied by nervous symptoms:

The first of these subjects complained of worries, fears, tension, and fatigue. It was considered that her conditions of housing were producing anxiety and frustration, which increased the disability due to her organic state (osteoarthritis). In the second, depression, lack of energy, and poor sleep appeared about one month after the onset of brachial neuralgia and seemed to be a consequence of pain and limitation of activity.

In the third, a right-sided cervical rib had begun to cause symptoms a few days after a fall on the right hand. On examination the patient also admitted to shakiness, depression, disturbing dreams, and fear of the dark and of open spaces. These were discovered to accompany sexual maladjustment with dyspareunia and fear of pregnancy. They appeared unrelated to the rheumatic complaint.

In the fourth subject pain from periarthritis of the right shoulder was accompanied by fatigue, headache, and insomnia. The shoulder condition followed a fall a few months before the time of examination; the other symptoms had been present over many years and were the expression of a lifelong neurotic state.

The fifth subject, with a twelve-months history of rheumatoid arthritis, complained of lassitude, depression, and disturbed sleep. She gave a history of previous nervous illness. In view of the common observation that rheumatoid arthritis may become manifest after emotional trauma, the circumstances of onset in this patient were carefully reviewed. No significant precipitating event was found, and the nervous symptoms were considered to be secondary to the arthritis.

In only one patient of the test group were there no associated nervous symptoms. With two possible exceptions the rheumatic condition in every patient in this group formed one component of a reaction pattern which was also expressed in disturbance of affect and behaviour. The pathogenesis of the condition in each patient is considered in more detail below.

Psychometric Findings.—(*a*) *Rorschach test:* This is a sensitive indicator of personality disturbance. Interpretation of records is a skilled task and cannot be reduced to a quantitative scoring method. For the purposes of this investigation the accompanying table of incidence of certain Rorschach signs of maladjustment was drawn up; it shows a greater degree of disturbance in the test group than in the control group taken as a whole. If the two control subjects with neurotic features on clinical examination are excluded the difference becomes more pronounced. More patients than controls showed evidence of difficulties in the emotional field: domination by emotional impulses or a morbid fear of and withdrawal from situations likely to arouse them. "Blocking"—complete failure to handle adequately such situations—was more often found. Awareness of alien forces within the personality of a sinister and threatening nature was commoner in the patient group

Results of Rorschach Test

	Responses < 15 or > 70	No Colour Response	Colour Response C Only	Rejections Other Than IX	Last 3 Cards			Content Categories Under 5	P. Responses Under 4
					Under 30%	Above 45%	Total		
Controls	4	4	—	5	6	—	6	6	7
Controls, without neurotic subjects	2	2	—	4	6	—	6	4	5
Patients	11	6	2	8	8	2	10	10	11

Signs of sexual maladjustment occurred more often. The various effects of anxiety on the test performance were shown to a considerably greater extent in the controls than in the patients' records.

(*b*) *Thematic Apperception Test* (selected series of cards): The patients showed in general a greater preoccupation with themes of violence, injury, crime and punishment, murder, and suicide. For example, one at least of the cards was interpreted as showing a murder by six of the patients, as against three controls; as showing a suicide by four patients, as against one control; and as showing some form of violence by five patients, as against one control. Themes of guilt after wrongdoing were also more frequent in the patients' records.

The material from the Rorschach and T.A.T. records will be used at a later date to build up a formulation for the pathogenesis of illness in the test group.

D. Physical Status

The control group showed the physical signs appropriate to the physical disorder from which they were suffering. The complaint was in general consistent in its expression and the discomfort was localized to one, usually anatomical, body area.

The test group complained in the main of diffuse and severe discomfort, inconstant in site, in degree, and in nature. The terminology used to express the complaint was often bizarre. The distribution of the discomfort did not correspond to that of a recognized physical disorder. Physical signs of a skeletal abnormality were absent. To say, however, that no physical signs can be elicited is not usually correct. A typical reaction to examination was found. Tenderness was often diffuse and due to skin hyperaesthesia. The patients found relaxation difficult, and muscular tension had often to be overcome before full joint movement could be demonstrated. Deep reflexes were exaggerated. In several cases the patient took the examiner's hand and applied it to the painful portions of her body.

X-ray examination and sedimentation rate estimation in the test group showed no abnormality.

Pathogenesis

The absence of physical signs of organic disease and the clinical characters of the complaint, especially the distribution of the discomfort and the significance of the complaint in the patient's total reaction, place this type of rheumatism in a class apart from the hitherto recognized rheumatic disorders. Its formulation as a "psychosomatic" condition cannot, however, be considered as adequate unless the morbid physiology underlying the physical symptoms can be articulated with the psychodynamics of the patient's emotional state.

In the test group a tentative formulation of the pathogenesis could be arrived at in 13 of the 15 cases. A fuller account embodying the psychometric material and further physiological data will be published later; a summary of each case, necessarily simplified, is here given.

Miss A., aged 24, is described as "fussy, upright, proud; holds herself very upright." Mother: rheumatism; nervy, quick-tempered. Mother died in 1943; in 1945 father began to carry on a liaison with another woman, who drank. Patient objected to this, and there were quarrels, after which she felt very disturbed and tense. Her feelings "seem to bottle up inside." Onset of generalized pains, mainly neck and spine, in 1945. Pathogenesis: somatic expression, perhaps in muscular tension, of strong moral resentment of father's behaviour.

Mrs. B., aged 50, was nervous and timid in childhood; illness diagnosed as chorea. Nail-biting and enuresis until 11 years. Home unhappy. Marriage unsatisfactory; husband has "bad nerves" and accuses her constantly of infidelity. "Prolapse of womb" in 1946; after this she was convinced that "something was wrong inside" which had not been discovered. Pain in the right side and back began at this time, accompanied by hysterical outbursts. Pathogenesis: nosophobia.

Mrs. C., aged 45. Father: violent, unstable. Mother: nervy. As a child patient was timid and nervous and afraid of father. Marriage happy; wanted large family but had only one child. Operation at 30 for sterility; at 42, uterus and one ovary removed. Very distressed by this; felt inferior to other women. Backache began after the operation. Rorschach: gross disturbance by a sinister fantasy life, with aggressive and sadistic trends. Pathogenesis: somatic expression of self-punitive trend at her failure to bear children.

Mrs. D., aged 39, is an unstable, dull, shallow person who nevertheless has considerable determination and can usually get her way with people. Married during the war and left her husband next morning as she could not tolerate sex relations. Felt strongly the need for home and security. Onset of pain in back and perineum while living alone in London. This resisted all treatment until she found a congenial job with friendly people. Pathogenesis: somatic expression of intense self-concern and need for affection.

Miss E., aged 27. Father: rheumatism; bad temper. Mother: rheumatism; irritable. Patient a diligent, conscientious, active person. Is compelled by circumstance to do a good deal of housework as well as her job, and resents it. Both parents are difficult and obstinate, and there are continual family quarrels. Onset of generalized pains after an increase in household duties on her sister's marriage. Pathogenesis: somatic expression of suppressed resentment of her parents' attitude and demands.

Mrs. F., aged 42, was nervous and timid as a child; enuresis till 12 years. Regular dysmenorrhoea; after marriage, disinclination for sex. Onset of pain in rectum while on evacuation from London during the war; this was relieved by injection for haemorrhoids, but she was told that the "neck of the womb was out of order." Became convinced that she had some disease of the uterus, probably cancer; pain in rectum returned, with backache. Pathogenesis: nosophobia.

Mrs. G., aged 53. Father: rheumatism "all over"; irritable. Mother: rheumatism. Patient nervous and worrying as a child. Family unhappy. All her life has had to look after invalids; her husband died of tuberculosis after a long illness. Had one child which lived only two weeks; pain in the back at this time. Had to take care of a sister with Parkinsonism who did not appreciate what was done for her; exacerbation of rheumatism at this time. Depressed; considers her life is empty. Pathogenesis: somatic expression of anxiety with guilt over her aggressive impulses towards sister.

Mr. H., aged 23, was wayward and delinquent as a boy; preferred sport to work. Served in R.A.M.C. during the war, much of the time abroad. Found this "nerve-racking"; longed for home. Onset of pain in left chest during a football match, probably from a minor injury, in Singapore after return from home leave. After demobilization, dissatisfied with civilian job and living conditions. Pathogenesis: prolongation of physical symptom due to frustration and discontent.

Mrs. I., aged 42. Mother: rheumatism; very concerned over children's health. Patient is married and has four children, who are a constant worry to her lest they fall ill or are injured. Never lets them out of her sight, but is impatient if they resist her—"would like to take a knife to them." Onset of backache during a depressive illness. T.A.T.: preoccupation with death and suicide. Pathogenesis: somatic expression of tension from markedly ambivalent feelings towards children.

Mrs. J., aged 33. Father: backache, nervous. Mother: "curved spine." Patient always wished to do well in business and was happiest when managing a public house. Has always been irritable, tense, and unable to relax. Marriage fairly satisfactory, but she had dysmenorrhoea, distaste for sex relations, delayed conception, and vomiting in pregnancy. She sleeps badly, and while half awake sees vivid pictures of death

and injury. T.A.T.: preoccupation with and fear of sadistic impulses. Onset of pain in back, legs, and hands during last pregnancy. Pathogenesis: somatic expression of discontent from thwarted masculine aims and ambitions.

Mrs. K., aged 32. Father: rheumatism in head, arms, shoulders, knee; "always rubbing himself"; "nerves in the head." Patient "takes after father very much." Onset of aching pain in back, arms, and legs while living away from London during the war. No immediate source of emotional tension found. Patient very preoccupied with her complaint and sure she is going to be crippled with rheumatism, as her father and aunt were. Probable pathogenesis: nosophobia.

Miss L., aged 19. Father died when patient was 11. Brought up by mother, with whom she has always got on badly. Patient described as "hysterical; flares up easily." Both she and her mother have violent tempers. Patient says she wants to leave home, yet is clearly very dependent on mother. Has one boy friend, with whom she quarrels continually. They became engaged, hoping that this would ease things; the quarrels ceased, but the patient developed pain in shoulders and arms, with odd sensations in the limbs. Pathogenesis: somatic expression of anxiety from two main conflicts—over dependence, and over relation to fiancé; with utilization of illness as a means of avoiding marriage.

Mrs. M., aged 52. Father: ill-tempered and unstable; left home. Patient strong and active; reared in a convent. Marriage difficult; husband a chronic invalid who died, leaving her with five young children. She had to work to support the family. Onset of pain in back and limbs after a confinement in her early thirties. Repeated mild attacks of depression, ascribed to worry of looking after children. T.A.T.: marked preoccupation with theme of injury and reparation as between mother and child. Probable pathogenesis: somatic expression of guilt over care of children.

Miss N., aged 59. Father: nervous, temperamental. Mother: rheumatism. Patient has energetic and forceful disposition, with strong intellectual and social ambitions, which have never been realized. At about 24 she began to suffer from insomnia with "visions," in which she could see herself as a crowned queen; with this, she felt irritation under the skin. At about 50 pain began in knees, ankles, and fingers, worst during the night, when she cannot sleep. T.A.T.: preoccupation with and fear of sadistic impulses. Pathogenesis: somatic expression of suppressed resentment from thwarted ambition, precipitated by menopause.

Miss O., aged 43. Mother: fainting attacks; chronic fatigue; dominating and strict with her children. Patient active, vigorous, ambitious, and successful; reached her goal—to be a head mistress. Onset of backache during the war, at a time of especial stress while she was concerned over danger to her mother from the air raids. Had to give up her career to look after mother because of illness. Pathogenesis: somatic expression of anxiety from conflict over relation to mother.

Diagnosis and Treatment

The principal diagnostic features of psychogenic rheumatism appear to be in (1) expression of complaint; (2) area of discomfort; (3) failure to conform to an established organic syndrome; (4) setting of the illness in relation to the patient's life situation; and (5) lack of response to physical treatments.

The treatment and disposal of patients regarded as suffering from psychogenic rheumatism has always provided a real problem to the clinician. It is part of the syndrome that they do not respond to treatment which is limited to physical measures. It seems clear that to these patients their suffering is something very personal and valuable; it makes them important, interesting, and worthy of sympathy, and is a protection against an unkind world. To treat them with passive physiotherapy is to acquiesce in their own diagnosis of disease and to allow it to take a deeper root. Such treatment usually gives temporary relief but does not cure; after a time it may come to be indispensable to the patient. Physiotherapy which is painful may remove the symptom; another symptom will then take its place. Injections of a local analgesic may be tried; they generally have a dramatic effect. Even as little as a few drops of 1% procaine may lead to fainting and hysterical manifestations.

One of us has attempted to treat the patients in groups by general ultra-violet irradiation followed by exercises; this method has had some success. Group psychotherapy of selected patients has now been started and has already given encouraging results. It is probable that an approach along these lines will prove to be the most profitable measure.

Summary

An investigation by a physician, a psychiatrist, and a psychologist of a group of patients suffering from a rheumatic disorder without signs of organic disease is described; a comparison with a control group is made.

In the former group the disorder was found to have certain special characters; in most cases the onset and course of the condition could be correlated with emotional disturbance. The condition seems to merit recognition as a clinical entity: it may be described by the term "psychogenic rheumatism."

We are indebted to Dr. T. A. Munro for his co-operation and advice; to Dr. K. W. N. Palmer, of the Department of Physical Medicine at Guy's, for his assistance with the control patients; and to Professor Aubrey Lewis and Dr. J. L. F. Maine for helpful suggestions.

A CASE OF RHEUMATOID ARTHRITIS SIMULATING PYOGENIC INFECTION

BY

D. S. SHORT, M.D., M.R.C.P.

Medical Registrar, Southmead Hospital, Bristol

The rarity of high fever in rheumatoid arthritis may be judged from the fact that Bannatyne (1896) on one occasion recorded a temperature of 105° F. (40.6° C.). This observation was later quoted by Garrod (1907) and by Jones (1909) as still unrivalled. Modern authors confine themselves to the statement that the temperature may rise to 102–103° F. (38.9–39.4° C.) and that a slight pyrexia may persist for several weeks.

The highest leucocytosis recorded in an uncomplicated case appears to be the figure of 15,800 mentioned by Erving (1903). Most modern writers omit all reference to the possible occurrence of a marked leucocytosis, and Gibson (1948) declares that "an increase of over 12,000 leucocytes per c.mm. is rare."

The following case is more reminiscent of the disease as seen in children, when fever and general symptoms may be present for weeks or months before definite articular manifestations make their appearance and fever and leucocytosis may be so marked as to simulate a pyogenic infection or leukaemia.

Case Report

The patient, a clerk aged 26, had previously been healthy save for a succession of sore throats.

He was first seen at Southmead Hospital on Jan. 2, 1948, when he gave a history of having had a sore throat nine weeks previously, accompanied by fever and pains in many joints, which had not become swollen. Fever with profuse sweating had persisted, and a temperature chart which he produced showed an evening rise varying between 101 and 103° F. (38.3 and 39.4° C.) over the past two and a half weeks.

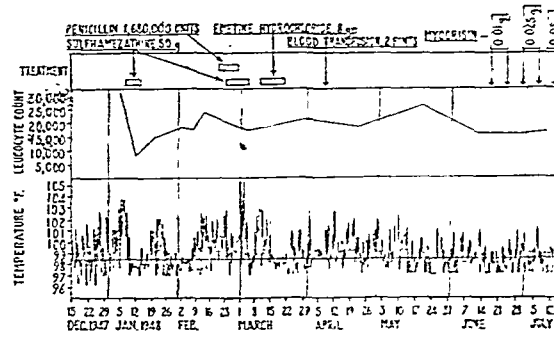
On examination he was seen to be thin and pale. His temperature was 101.2° F. (38.4° C.) and the skin warm and moist. The pulse (90–120) was accelerated in proportion to the fever, and the B.P. was 130/80. The only joint affected was the left elbow, which showed a 30-degrees limitation of extension. There was no local heat, swelling, or tenderness, though muscle spasm was pronounced. Examination of all other systems was entirely negative, and no nodules were found. There was a soft systolic murmur at the apex.

Three days after admission an effusion developed in the left knee, and the metacarpo-phalangeal joint of the right thumb also became painful. A blood count revealed a leucocytosis of 30,800 (neutrophils 88%, lymphocytes 8%, metamyelocytes 4%); Hb, 72%, red cells, 3,790,000. Two blood cultures were sterile, and agglutinations to *Salmonella typhi, S. paratyphi* A and B, and *Brucella abortus* were negative. Radiographs of the chest and left elbow were normal. No abnormality was found in the urine, although a trace of albumin appeared in several subsequent specimens. No malaria parasites were found in the blood. The Wassermann reaction and Paul–Bunnell test were negative, and intravenous pyelography revealed no abnormality.

On the evening of Jan. 7 the patient had a temperature of 103.6° F. (39.8° C.) and appeared critically ill. It was considered justifiable to employ chemotherapy empirically. "Sulphamezathine" was accordingly given in full doses for a week, to a total of 50 g. By the time the drug was discontinued he appeared much improved: the effusion in the left knee had subsided, the temperature had been subnormal for five days, and the leucocyte count had fallen to 8,700.

During the following week the temperature started to rise again, until on Jan. 22 it reached 102° F. (38.9° C.). The leucocyte count reached 15,000 and the E.S.R. was 35 mm. in the first hour. Two further blood cultures were negative. A radiograph of the spine and long bones showed no evidence of osteomyelitis or other bony disease. An evening temperature of 102° F. was maintained for 72 hours, then gradually subsided to normal, where it remained for nine days. At the end of this time the patient felt well and did not complain of joint pains. The leucocyte count of 17,800 nevertheless revealed that all was not well.

The temperature started to mount on Feb. 6, and by Feb. 19 the patient was again seriously ill, with a leucocytosis of 24,000. Penicillin was begun in a dosage of 30,000 units three-hourly, and as there was no response within four days this drug was supplemented by sulphamezathine in full doses for six days. For three days the temperature fell to a lower level, but on the fourth day he had a rigor and it rose to 105.2° F. (40.7° C.). On the next two days there were further rigors, and temperatures of 104 and 105.2° F. (40 and 40.7° C.) were recorded. Forty-eight hours later the patient was once again afebrile.



Further bouts of fever occurred during the next four months, and the temperature did not subside finally until the middle of July. During the first eighteen weeks in hospital the only constant physical sign was limitation of extension of the left elbow, with spasm and progressive wasting of the muscles above and below the affected joint. This and other joints were repeatedly *x*-rayed, with negative results until May 14, when periosteal changes were apparent around the neck of the left radius. Many joints were affected for short periods from an early stage in the course of the disease. At the end of February the left wrist and the proximal interphalangeal joints of the left hand became swollen and painful for a few days. Early in March there was pain on movement of the cervical spine, which persisted for about a fortnight. Later in the month both shoulders became painful for a week. In the middle of April both wrists were swollen and the proximal interphalangeal joints of the fingers were stiff for several days.

On May 17 more persistent changes appeared. The metacarpophalangeal joints of the left hand became swollen, red, and painful. At this time the leucocyte count rose to its second highest figure, 26,200. Ten days later the left wrist was inflamed and movement of the right wrist was found to be restricted. Thenceforward the typical deformity of the hands developed rapidly, and by the end of June radiological appearances characteristic of rheumatoid arthritis were apparent. None of the other joints, with the exception of the left elbow noted above, showed any radiological changes.

During the last week of February the patient complained of great soreness in the throat and pain on swallowing. The pharynx was injected, but no pathogens were isolated from the nose and throat swabs. Early in March definite hepatic tenderness became evident and there was an increase of urobilin in the urine. The van den Bergh reaction was negative, but the serum alkaline phosphatase was raised to 26.1 units. The serum albumin was 3.2 g. % and the serum globulin 4.1 g. %. In view of these observations, and bearing in mind that the patient had seen tropical service, amoebic hepatitis was considered. Emetine was tried empirically, 8 gr. (0.52 g.) of the hydrochloride being given over a period of ten days, but without benefit. In April one of the left axillary lymph glands became enlarged and was removed for biopsy. Non-specific inflammatory changes only were found.

Therapy and Progress

Sodium salicylate had been given for several weeks before admission and was administered again, without benefit, while the patient was in hospital. (For other therapeutic details, see Chart.) On July 29 he was transferred to the Royal National Hospital

Record of temperature, total leucocyte count, and treatment.

for Rheumatic Diseases, Bath, for further treatment. On admission his temperature was found to be 101.5° F. (38.6° C.) and for three weeks there was an evening rise of two or three degrees. He was given a transfusion of 2 pints (1.14 litres) of packed red cells. Other therapeutic measures included rest plasters for his hands at night, exercises in the pool, and mud-packs. Gold therapy was continued in the form of "auro-calcium," 20 mg. per week, rising later to 50 mg. At the end of November, when he was readmitted to Southmead Hospital for tonsillectomy, he looked remarkably well. His weight, which during April and May fell to 6 st. 12 lb. (42.6 kg.), had risen to 9 st. 9 lb. (60.5 kg.), and he had recovered a full head of hair, much of which had fallen out during his long illness. The only disability apparent was slight ulnar deviation of both wrists, with considerable limitation of movement in all directions. There was also periarticular thickening of the metacarpo-phalangeal and proximal interphalangeal joints of both hands, together with wasting of the intrinsic muscles. Radiographically, the carpus showed marked decalcification and narrowing of the joint spaces. All other joints (including the left elbow) showed a full range of painless movement.

Summary

A case of rheumatoid arthritis is described in which bouts of high fever occurred over a period of three months and of low-grade fever continued for a further four months before the diagnosis was evident. On two occasions a temperature of 105.2° F. (40.7° C.) was recorded after a rigor.

The highest leucocyte count was 30,800, recorded on admission; the next highest was 26,200 eighteen weeks later.

My thanks are due to Dr. G. D. Kersley for his help and for details of the patient's treatment and progress while under his care in the Royal National Hospital for Rheumatic Diseases, Bath; to Dr. D. H. Davies, under whose care the patient was admitted to Southmead Hospital, for advice and criticism; and to Dr. P. Phillips, the medical superintendent, for permission to publish.

FIBROCYSTIC DISEASE OF THE PANCREAS*

BY

W. J. MATHESON, M.D., M.R.C.P., D.C.H.

(From the Paediatric Unit, St. Mary's Hospital, London)

[WITH PHOTOGRAVURE PLATE]

Although the American literature on this subject is now fairly extensive there have been few reports from this country. Doubtless many cases have gone unreported, but there is still a widespread belief that the disease is rare, and personal experience has shown that it is often misdiagnosed. The only large series described here is that of Bodian (1946), who reported 30 cases. Henderson (1945) recorded one case and MacGregor and Rhaney (1948) two cases in siblings. Previously, under the title of congenital steatorrhoea, Miller and Perkins (1920) and Cockayne (1933) each described one probable case of fibrocystic disease, and Clarke and Hadfield (1924) a proved case, for necropsy showed the pancreatic lesions which are now associated with this disease. It is unlikely that the case described by Garrod and Hurtley (1913) under the same title was one of fibrocystic disease, since Garrod (1920) subsequently reported that this patient was of normal development and activity at the age of 14 years.

Although the association of pancreatic disease and steatorrhoea had been known for over a century it was not until 1905 that Landsteiner described the pancreatic lesions now associated with fibrocystic disease. Passini (1919) first reported a case in which the association of the digestive disturbance and the pathological lesion of the pancreas was recognized. Parmelee (1935) described the cases of two patients with congenital steatorrhoea who died of bronchopneumonia, and in both of whom necropsy revealed cystic fibrosis in the pancreas; he had found in the literature only four cases with a similar history and post-mortem findings. Blackfan and Wolbach (1933) had, however, described six similar cases among 10 reported as cases of vitamin-A deficiency in infants, and Harper (1930) one case among two reported under the title of congenital steatorrhoea.

*Based on a thesis submitted to the University of Edinburgh for the degree of M.D., September, 1948.

Harper (1938) reported eight further cases under the same title, in five of which necropsy showed typical pancreatic lesions, and Blackfan and May (1938) described 35 cases with similar pancreatic lesions which in lesser degree they had observed in a further 200 cases; but they considered that it was not possible to determine accurately dependable diagnostic features in life in these cases. Fibrocystic disease of the pancreas was, however, becoming recognized with increasing frequency at necropsy; and, finally, Andersen (1938) showed that the disease was a definite and common clinical entity with a characteristic course and clinical history. She has since written extensively about the disease in all its aspects, and recently gave in this country a summary of her work (Andersen, 1949).

Case 1

This patient, a boy aged 10 (Fig. A), was first seen at the age of 8. Since birth his stools had been bulky, loose, pale, and offensive. Despite a good appetite and an adequate diet, he had never gained weight well. An irritative cough had been present since the age of 2 years, and had become worse and been accompanied by purulent sputum in the past nine months since an illness diagnosed as pertussis and bronchopneumonia. When 2 years old he was taken to another hospital, where coeliac disease was diagnosed. Dietary treatment for two years brought no improvement, and the diagnosis was altered to tabes mesenterica when his Mantoux reaction was found to be positive and calcified glands were seen in the abdomen at laparotomy performed on account of recurrent abdominal pain. He had had bronchopneumonia at 2 weeks and rectal prolapse at 6 months. His parents were not blood relations. One sibling aged 8 months is alive and well. The patient's weight was 44 lb. (19.96 kg.) (average, 57 lb.—25.85 kg.); height 48 in. (122 cm.) (average, 51 in.—130 cm.). His abdomen was prominent and his fingers were clubbed. Chest: percussion note hyperresonant; persistent crepitations in right lower and mid zones.

FIG. A.—Case 1 (on left) with normal boy of same age.

Investigations.—Duodenal juice contained no trypsin. Microscopical examinations of the stools revealed numerous fat globules and completely undigested muscle fibres; the fat content was 50%, of which 80% was split fat. Nitrogen excretion on a normal diet was 4.47 g. per day in faeces and 7.8 g. in urine. Blood counts showed no anaemia, but persistent polymorphonuclear leucocytosis. The predominant organism in the sputum was a penicillin-sensitive pneumococcus. Radiography of the chest showed emphysema with a generalized bronchitic appearance and parenchymal changes at the right base.

Progress and Treatment.—For 18 months he has been treated with a low-fat, high-protein, and high-carbohydrate diet and 30 g. of casein hydrolysate and 16 g. of pancreatin in the form of enteric-coated capsules and extra vitamins. He has gained only 4 lb. (1.81 kg.) in weight and 2½ in. (6.25 cm.) in height. At first his activity was greatly increased, but accesses of the pulmonary infection, although relieved by penicillin inhalations, have recently been occurring so often (about once a month) that his activity is now about the level maintained before specific therapy was started. Stools are now formed and not very offensive. On the same diet faecal nitrogen has been found to be diminished when pancreatin is given.

Case 2

A boy aged 2 years was admitted to hospital on Sept. 13, 948. Since the age of 2 months he had wheezed continually; diagnosis of asthma was made and never altered. One month efore admission he began to cough and lost weight and nergy. Rectal prolapse had occurred repeatedly in the past wo months. Despite a good appetite, he had never thrived, is weight at 8 months being 15¼ lb. (7 kg.) and at 1 year 8½ lb. (8.4 kg.) (birth weight was 7½ lb.—3.4 kg.). From the ge of 6 months or so his stools had been frequent and nformed, bulky, and very offensive. He was the third child. he eldest died of acute bronchitis at 11 weeks. The second, ged 5 years, is alive and well. A paternal aunt, who had ever thrived, died at 16 days.

On examination his temperature was normal, pulse 120, and espirations 32; he was dyspnoeic, with frequent paroxysmal oughing. His weight was 21 lb. (9.5 kg.) (average, 27 lb.—2.2 kg.); height, 30 in. (76 cm.) (average, 33 in.—83.5 cm.). hest: percussion note hyperresonant; rhonchi and crepitaions in all areas. The liver was palpable two fingerbreadths elow the costal margin in the nipple line.

Investigations.—Numerous fat globules and undigested nuscle fibres were found in the stools; the fat content was 0%. A laryngeal swab revealed *Staphylococcus aureus* sensiive to streptomycin only. Duodenal intubation was unsuccessul. Blood counts showed a progressive fall in haemoglobin o 75% on Oct. 28; there was a persistent polymorphonuclear eucocytosis up to 40,000 per c.mm. Radiographs of the chest howed increasing spread and confluence of bronchopneumonia n all areas of the lung fields.

Progress and Treatment.—Wheezing disappeared after two eeks, but despite the use of streptomycin, given by inhalation nd intramuscularly, the cough became more severe, crepitaons persisted in the lungs, and a swinging temperature soon eveloped and persisted. Cyanosis was present in the fortnight efore death on Nov. 19. His appetite had been good for x weeks, and on a low-fat diet with extra protein and 26 g. f casein hydrolysate and 8 g. of pancreatin (in the form of nteric-coated granules) daily his weight had risen to 22 lb. 9.98 kg.) but then fell progressively. His stools had continually een frequent, unformed, and very offensive. The liver had emained enlarged.

Post-mortem Report.—There was much mucopurulent naterial in the air passages, and in the lungs extensive ronchopneumonia with bronchiolectatic abscesses. The ancreas appeared normal macroscopically. The liver was nutmeg," and the appendix was thickened. Microscopically, he pancreatic ducts were considerably dilated and filled with osinophilic material, and there was much surrounding fibrosis; he lumen of the appendix was filled with eosinophilic material ontinuous with that in the dilated glands of the wall (Plate, ig. 1). Similar lesions were seen in the mucous glands of he trachea and bronchi (Fig. 2), the salivary glands, the uodenal wall, and the periurethral glands.

Case 3

A girl aged 2 years was first seen in January, 1947, at the ge of 21 months, with rectal prolapse, which was attributed o inadequate intake of vitamin D. Her weight was then 4 lb. (10.88 kg.). When next seen, a month later, she had eveloped a slight cough and had lost weight despite a good ppetite. She was admitted early in May, 1947, for correction f the prolapse, but was discharged five days later as she was nought to have pertussis. At home the cough became more evere, the weight-loss was accelerated, and she was readmitted t the end of May. Even in infancy her gain in weight had ever been satisfactory, although her appetite was so good hat she was fed three-hourly with amounts prescribed for our-hourly feeds. Her stools had always been bulky, pale, nd very offensive.

She was the fourth child of healthy unrelated parents. Her hree siblings had all died of bronchopneumonia before the ge of 6 months; none had thrived, and all had had very offensive stools. The maternal grandmother had lost five out of eight children in infancy from unknown causes. The paternal grandmother had lost six of 12 children in infancy—four at birth and two of pneumonia during the first year.

On May 22 her temperature was 101.6° F. (38.7° C.), respirations 64, pulse 128, weight 18¼ lb (8.28 kg.) (average, 24 lb.—10.88 kg.). She was wasted and dyspnoeic. Chest: Fine crepitations in all areas. The abdomen was protuberant. The liver was enlarged to the umbilicus. The spleen was not palpable.

Investigations.—The faecal fat amounted to 49%, 86% of it being split fat. Blood counts showed a progressive anaemia. Three attempts at duodenal intubation were unsuccessful. Mantoux, negative at 1 in 1,000. Serum proteins (June 25) were 7 g. %—albumin 2.8, globulin 4.2. Chest radiographs showed increasing bronchopneumonic changes.

Progress and Treatment.—Sulphamezathine and penicillin failed to control the respiratory infection. Cyanosis was only temporarily relieved by oxygen. The stools were frequent, unformed, and very offensive; appetite was never good, and weight fell progressively. Pancreatin given in the last three weeks had no appreciable effect. Peripheral oedema, unrelieved by blood transfusion and intravenous "casydrol," appeared four weeks before death, and petechiae terminally.

Post-mortem Report (July 22).—Much mucopus in the air passages. In the lungs marginal emphysema was present, with extensive bronchopneumonia and numerous bronchiectatic abscesses in practically all areas. The pancreas on section showed dilated ducts. The liver was large and pale. Microscopical examination showed gross dilatation of pancreatic ducts filled with eosinophilic material, much surrounding fibrosis, and almost complete disappearance of acinous tissue. There was bronchopneumonia with, in places, destruction of bronchial walls and dilated bronchial glands. The liver showed gross fatty degeneration.

Case 4

A girl aged 4 months was transferred on July 16, 1948, from another hospital, where she had been treated for six weeks for bronchopneumonia without improvement. Despite a good appetite she had never thrived, and her stools had always been frequent and offensive. At 3 months she developed pneumonia, which did not respond to treatment with sulphonamides and penicillin. She had three siblings alive and well. A maternal uncle, who had never thrived, died at 10 years of "consumption of the bowels."

On examination on July 16 the temperature was 99° F. (37.2° C.), respirations 48, weight 8 lb. 15 oz. (4 kg.) (expected weight, 12½ lb.—5.67 kg.). She was wasted; the abdomen was prominent. There was dyspnoea with frequent cough. Chest: percussion note impaired at left base; fine crepitations audible over the entire left chest.

Investigations.—Duodenal juice contained no trypsin. Faecal fat: (*a*) on skimmed milk 40%, (*b*) on half-cream milk with pancreatin 21% (96% split). A laryngeal swab contained predominantly a penicillin-sensitive *Staph. aureus*. Hb was 65%. Radiography of the chest showed left basal consolidation.

Progress and Treatment.—Penicillin was continued, but the respiratory trouble spread. Appetite was poor. Stools were always frequent, bulky, and very offensive. She died on Aug. 4.

Post-mortem Report.—The immediate cause of death was bronchopneumonia. The pancreas was smaller than normal, was nodular, and presented an increased resistance to section. Microscopically, typical changes were seen in the pancreas and salivary glands.

Case 5

A boy aged 4 months was admitted to hospital on Aug. 3, 1948. His appetite had always been good, but weight-gain had never been satisfactory (his best weight was 8 lb. (3.63 kg.) at three months). Stools had always been frequent but not noticeably offensive. A frequent dry cough had been present since birth.

On examination the temperature and respirations were normal and the weight 7 lb. 11 oz. (3.48 kg.) (expected weight,

12¼ lb.—5.55 kg.). Mediastinal shift to right with hyperresonant percussion note over left chest.

Investigations.—Three attempts at duodenal intubation failed. Faecal fat (on full-cream milk), 72% (50% split). Laryngeal swab revealed *Staph. aureus*. Blood counts showed a progressive anaemia.

Progress and Treatment.—Ten days after admission he developed a pulmonary infection which did not respond to penicillin. Appetite was very good, and on a skimmed-milk diet with pancreatin and hydrolysates weight increased slowly to 8 lb. 10 oz. (3.91 kg.). Stools were always bulky, frequent, and very offensive.

Post-mortem Report (Sept. 21).—The immediate cause of death was bronchopneumonia. The pancreas was normal externally, but dilated ducts were seen on section. Microscopically, typical changes were seen in the pancreas, salivary glands, and bronchial and intestinal walls.

Case 6

A girl aged 5 months, an only child, was admitted to hospital on Nov. 1, 1947, with right basal pneumonia. She had had a cough since birth, but weight-gain had been satisfactory, and she had reached 12¼ lb. (5.55 kg.) (expected weight, 12 lb. —5.44 kg.) when pneumonia developed two weeks before admission. Chemotherapy and antibiotics failed to control the respiratory infection, and although she ate well her weight fell. Stools were first noticed to be offensive two weeks after admission; the fat content was 40% (on half-cream milk feeds).

Post-mortem Report (Dec. 17).—The immediate cause of death was bronchopneumonia. The pancreas was smaller and more nodular than normal. On the surface of the liver were small nodules up to 2 mm. in diameter. Microscopically the pancreas showed the typical changes in an advanced stage (Fig. 3). In the liver the nodules were seen macroscopically to consist of cirrhotic areas in which were numerous bile ducts filled with eosinophilic material. Similar lesions to those in the pancreas were found in the salivary glands and in the duodenal wall (Fig. 4).

Case 7

A girl aged 16 months was transferred on July 30, 1948, from another hospital, where she had been treated for two months for coeliac disease without improvement. Weight-gain was never satisfactory, and from the age of 4 months her stools were bulky and offensive. This abnormality became more noticeable at 1 year. She had had bronchitis at 8 months.

On July 30 her weight was 15¼ lb. (6.92 kg.) (average, 22 lb. —9.98 kg.). She had a coeliac appearance. Her chest was normal. Duodenal juice showed tryptic activity in undiluted juice but not in a dilution of 1 in 10. Faecal fat: (*a*) on a normal diet, 60% (75% split; (*b*) on a low-fat diet with pancreatin, 15%. With specific dietary treatment she gained 3 lb. (1.36 kg.) in three weeks. Her stools were always unformed and offensive.

Discussion

The seven cases described were seen between June, 1947, and September, 1948. To ascertain the hospital incidence it is necessary to exclude Cases 4 and 5, which were transferred from other hospitals because of our known interest in fibrocystic disease; the remaining five cases occurred among 240 medical admissions to the children's ward—an incidence of 2%. Andersen (1938) found evidence of the disease in 3% of all necropsies on infants, and Bodian (1946) in 3.4% of 500 necropsies on children. The disease therefore is by no means uncommon. The failure to appreciate this prior to 1938 is undoubtedly due to the fact that bronchopneumonia, the usual cause of death, was taken to be an adequate cause and consequently the pancreas was not sectioned.

The evidence points to the disease being inherited (Andersen, 1949). In this series no other proved case has occurred in an affected family, but there is presumptive evidence of the disease in the family history of Case 3 and suggestive evidence in Case 2. The inheritance may be explained by incomplete dominance: Fisher (quoted by Cockayne, 1947) has shown that many dominant defects are gradually becoming recessive, this being brought about by the selection of genes which prevent a dominant condition becoming manifest when in the heterozygous state; moreover, a defect may behave in one family as a recessive and in another as a dominant.

The pancreatic lesions were formerly sometimes ascribed to dehydration, but Farber (1942) disproved this. Blackfan and Wolbach (1933) first advanced the hypothesis that the were caused by inspissation of viscid secretion in the ducts this was confirmed by Farber (1942), who reproduced the lesions in kittens by vagal stimulation. It remains to be seen if similar experiments will reproduce the lesion occurring in other organs also, and the cause of the abnormal secretion has yet to be determined.

Farber (1944) reported the finding of dilated glandular structures in both the respiratory and the intestinal tracts he concluded that the disease affected all mucus-secreting glands, the lesions being caused by inspissation of viscid secretion, and that it was the loss of normal mucus from the bronchial tree that was responsible for the susceptibility to pulmonary infections. Bodian (1946) also has stressed that this is a pluriglandular disease, as have Continental workers (Glanzmann, 1946; Riniker, 1946). Andersen (1949), however, while accepting Blackfan and Wolbach's explanation for the pancreatic lesions, considers that the pulmonary infection is conditioned by dietary deficiency, and that the lesions observed in the bronchial walls are secondary to infection. But this explanation does not suffice for the similar lesions found in other organs in which there is no infection; moreover, dogs in whom the pancreatic duct has been tied did not die from pulmonary infections (Ivy, 1936). The pathological findings in this series have again confirmed the pluriglandular nature of this disease, and there seems little doubt that Farber's hypothesis is correct.

Earlier observers (Parmelee, 1935; Harper, 1938) considered that a high percentage of neutral fat in the stool indicated pancreatic disease. Andersen (1945a), however has shown that faecal fat can be split in the colon and outside the body by bacterial action, and Fourman *et al.* (1948) consider that increased nitrogen excretion in the faeces is the most reliable test of pancreatic steatorrhoea. Fat analyses of three-day collections of stools, as carried out in these cases, will usually detect steatorrhoea (Fourman *et al.*, 1948), but the determination of split and unsplit fat is of no diagnostic value (May, 1947).

Andersen (1938) showed that cases fell into three main groups: (1) cases of meconium ileus which present within a few days of birth with intestinal obstruction; (2) cases which present in the first six months of life with respiratory infections—nutritional difficulty is also present (this is the largest group); (3) cases which present later with nutritional difficulty as instances of the coeliac syndrome or with rectal prolapse or with chronic respiratory infection. The typical history is of a poor gain in weight despite an adequate diet and an excellent appetite, dating from early infancy. The stools are frequent, unformed, bulky, and very offensive; these abnormalities are more often noticed by mothers who have previously borne normal children, and usually date from early infancy. Sooner or later respiratory infection supervenes and dominates the picture.

Although it is generally agreed (May, 1947; Andersen, 1949) that estimation of trypsin in the duodenal juice is necessary to establish the diagnosis, nevertheless it is

desirable to make a diagnosis on clinical evidence whenever possible, and experience has indicated that this can be done. In all the present cases the diagnosis was made clinically and was never disproved by subsequent examination of the duodenal juice or by necropsy. The clinical picture is highly characteristic, but it must be emphasized that an accurate history is essential, and close questioning may be required to obtain this, as noted by Miller and Perkins (1920).

The disease should be suspected in all cases of chronic nutritional difficulty and chronic respiratory infection in children, and specific questions asked about appetite, weight-gain, the character of the stools in regard to number, size, and smell, the exact date of onset of any abnormality noted, and the family history, especially of infantile deaths. In a number of cases the abnormality of the stools, while present from early infancy, becomes more obvious when solids are added to the diet or even later, and this overshadows the history. Cough may be present without signs of infection, and is then presumably due to efforts to expel viscid mucus from the bronchial tree. The clinician should himself examine the stools, for their offensive smell is characteristic. The typical history, associated with the clinical findings, enables a firm diagnosis to be made.

Sheldon (1948) considers that it is usually possible to distinguish coeliac from fibrocystic disease on clinical grounds alone. In typical cases, therefore, duodenal intubation is superfluous and should be reserved for cases in which the picture is not characteristic—e.g., Case 6. It is important to remember that in some children any chronic infection may produce steatorrhoea and that the association of bronchiectasis and steatorrhoea does not justify a diagnosis of fibrocystic disease without supporting evidence.

It is not only desirable but sometimes necessary to make a clinical diagnosis, since duodenal intubation has often been unsuccessful, and repeated attempts do not improve the condition of children already wasted. Moreover, the absence of trypsin from the duodenal juice is not pathognomonic of fibrocystic disease. Dr. G. M. Bull, to whom I am indebted for these particulars, has under his care two adults—brother and sister, aged 18 and 22 years respectively—who have suffered from steatorrhoea since early infancy. Recently duodenal intubation has shown a complete absence of trypsin in both, but there is no pulmonary infection. These patients are not suffering from fibrocystic disease as regarded generally. Their cases are, however, similar to the case reported by Garrod and Hurtley (1913). Either the underlying lesion may be a congenital stenosis of the main pancreatic duct or these cases may be analogous to that reported by Farber (1944) in which lesions typical of fibrocystic disease were found only in the lungs and liver; vice versa, there may be cases in which the pancreas is affected and not the lungs.

Treatment.—The diet used has been that recommended by Andersen (1949), but pancreatin has been more extensively employed than casein hydrolysates, since the latter are unpalatable and older children are loath to take them. It is unfortunate that hydrolysates are so unpleasant, since the evidence indicates that they are of more value than pancreatin (West *et al.*, 1946).

Results of Treatment and Prognosis.—Of the seven patients, five have died of bronchopneumonia and one of the survivors has extensive bronchiectasis. The prognosis therefore depends on the respiratory infection, and the failure of appropriate chemotherapeutic and antibiotic agents to control it has been most disappointing. Specific dietary treatment also has proved of limited value. Pancreatin does, however, seem to be of value in increasing the utilization of food, and this effect is especially noticeable in infants.

The number of cases reported here is small, but no evidence has been found to support Andersen's (1949) contention that appropriate chemotherapy, given early in the course of the respiratory infection, combined with specific dietary treatment, may result in the control of the infection. Personal experience of cases diagnosed before the onset of respiratory infections is limited, but Andersen's (1945b) evidence that most, when given specific therapy, do not contract chronic respiratory infections and develop normally is not fully convincing. In assessing the results of any therapeutic regime in this disease it is important to remember that the oldest proved case in the literature, aged 14½ years (Parmelee, 1935), was treated by a low-fat and high-protein diet only. Moreover, Cases 1 and 7 in this series showed that pulmonary infections in infancy do not invariably become chronic even without treatment. Also there are a few cases which, although they lack trypsin in their duodenal juice, do not develop pulmonary infections at all.

Since in the great majority of cases of bronchopneumonia in children a good response is obtained, the failure of chemotherapy to control the pulmonary infections in these cases suggests that unusual factors are involved. One unusual factor is the abnormality of the mucous glands of the air passages, and the treatment so far possible cannot be expected to influence this. The rational treatment would be to liquefy the mucus in the bronchial tree by some substance (e.g., hyaluronidase) aimed at restoring normal conditions in the respiratory system.

Summary

Seven cases of fibrocystic disease of the pancreas are described which occurred among 2% of routine admissions to a children's ward.

Inheritance by incomplete dominance is postulated.

The pathological findings have again confirmed that this disease affects mucus-secreting glands throughout the body.

The diagnosis can usually be made clinically provided an accurate history is obtained.

The results of treatment have been disappointing, since five of the patients have died of bronchopneumonia and one of the survivors has extensive bronchiectasis.

It is suggested that measures directed at liquefying the mucus in the bronchial tree might lead to more successful results than those generally at present obtained.

I wish to thank Dr. Reginald Lightwood for much helpful advice and criticism and for permission to publish these cases, except Case 5, for which I am indebted to Dr. Ursula James. I also wish to thank the staff of St. Mary's Hospital, Paddington, for carrying out the investigations; Mr. E. V. Willmott for the photomicrographs; and Mr. A. Evason for the clinical photograph.

FATAL CASE OF POLIO-ENCEPHALITIS DUE TO POLIOMYELITIS VIRUS

BY

G. H. JENNINGS, M.D., F.R.C.P.
Senior Physician, Edgware General Hospital

J. L. HAMILTON-PATERSON, M.D.
Pathologist, Edgware General Hospital

AND

F. O. MacCALLUM, M.D., B.Sc.(Toronto)
Director, Virus Reference Laboratory, Central Public Health Laboratory, Colindale

[WITH PHOTOGRAVURE PLATE]

The case of fatal polio-encephalitis described in detail below is reported because of its interesting clinical picture and because of the striking proof of the diagnosis by intracerebral inoculation in a monkey. The similarity of the lesions in the cord of the human victim to those in the monkey inoculated with a filtered saline extract from the child's brain and cord can easily be seen by reference to the illustrations.

Case Report

A well-developed child of 3½ years was admitted to Edgware General Hospital on Aug. 3, 1948. He had had pertussis at 1½ years, but had otherwise been well until he began to attend a nursery school one month before his admission. He was not happy at the school, slept irregularly at night, and was sleepy in the mornings. Three weeks before admission he had an illness of influenzal type lasting one day, during which he vomited and was febrile and drowsy. On July 31 he was said to have fallen from a swing, though apparently with no untoward effect. However, the next day he became drowsy and slept through much of it, would not eat, complained of abdominal pains, and vomited twice. During the night he awoke three times and complained of headache and pains in the back of the neck and in the legs. On Aug. 2 he still complained of the pains, and some weakness of the left side of the face developed, the face being drawn to the right. Although he was febrile and eager for fluids, he appeared to swallow with difficulty. He talked normally throughout the day. By evening he was generally stiff and showed a tendency to restlessness and twitching of the limbs. The bowels were constipated from that day to the end, and he again vomited once. On the day of admission he was not easy to rouse and would not speak; the restlessness and twitchings continued.

On admission he was very drowsy, toxic, and cyanosed. His temperature was 102° F. (38.9° C.), pulse 88, respiration 56. His tongue was moist but furred. The throat was not inflamed, but the tonsillar glands were palpable. There was pronounced stiffness of the neck and spine. Kernig's sign was not present and the legs were not stiff. His pupils were equal and reacted to light, though sluggish. The disks were normal. He had slight weakness of the left side of the face. No other apparent abnormality in cranial nerves was observed and no weakness was noted in the limbs. Tendon-jerks were absent in the left lower limb but brisk on the right side. Plantar response was extensor on the left side and indefinite on the right. No abnormality was noted in other systems.

Lumbar puncture showed clear fluid under normal pressure; total protein, 80 mg. per 100 ml.; Pandy +; white blood cells, 55 per c.mm (degenerate polymorphs 5%, lymphocytes 20%, large endothelials 75%); chlorides, 710 mg. per 100 ml.; no organisms seen; sterile on culture.

Overnight his condition had deteriorated rapidly, and when seen by one of us (G. H. J.) next morning (Aug. 4) he was almost completely unconscious. He was still toxic and cyanosed; respirations were stertorous, but the rate was only 22. His temperature was 98° F. (36.7° C.) and pulse 80. A tendency to show slight general convulsions was noted. The disks were normal, as were the pupils, apart from the persistent sluggish reaction to light. Neck stiffness was slight and Kernig's sign was negative. The face was now almost expressionless as a result of general weakness. The left side of the body, though still showing voluntary movement, appeared definitely weaker and more flaccid than the right. The tendon-jerks, though sluggish, were all elicited except the right ankle-jerk. The abdominal reflexes were all present. The left plantar response was still definitely extensor, but that on the right remained indefinite.

Lumbar puncture showed C.S.F. under very low pressure; no block; opalescent fluid; fibrin clot formed after 15 minutes; white blood cells, 195 per c.mm. (lymphocytes 86%, polymorphs 14%); red blood cells, 465 per c.mm.; normal sugar content; sterile on culture. A blood count showed: Hb, 90%; red cells, 5,090,000; white cells, 4,700 (polymorphs 68%, lymphocytes 28%, monocytes 4%.

A diagnosis of a neurotropic virus infection was made, and since the prodromal illness three weeks before admission was within the reported maximal incubation period of 35 days for the poliomyelitis virus it was considered that the case was possibly one of polio-encephalitis. The child's condition continued to deteriorate; the temperature became subnormal, the pulse rate increased to 120–136, and the respiration rate remained at 24–26. He died early on the following morning (Aug. 5) after many hours of complete unconsciousness.

Post-mortem Examination

This was performed five hours after death. The body was that of a normally developed male child.

Brain (1,350 g.).—Meninges normal. Surface of brain intensely congested. On section the cortex of the hemispheres was plum coloured, but showed no petechiae; white matter normal except for a few tiny petechial haemorrhages in the occipital lobes. The cerebellum, mid-brain, pons, and medulla were macroscopically normal.

Spinal Cord.—Macroscopically normal.

Skull.—Normal except for a small quantity of yellow glairy fluid in the right mastoid cavity. Films of this fluid showed occasional pus cells, and on culture a few colonies of *Bacterium coli* and *Streptococcus faecalis* were grown.

Comparison of Histological Lesions of Central Nervous System in the Case described and in the Inoculated Monkey

	Human	Monkey
Motor cortex, left	Congestion only	Early perivascular cuffing
" " right	—	Nil
Sensory cortex, left	—	Nil
" " right	—	Nil
Olfactory bulb	—	Nil
Basal nuclei	Few small areas of perivascular cuffing and very early neuronal changes	Perivascular cuffing and early neuronal degeneration
Brain stem		
Cervical cord ..	Marked perivascular cuffing. Slight cellular infiltration of anterior horns. Early neuronal degeneration	Marked perivascular cuffing. Cellular infiltration of grey matter most marked in anterior horns. All stages of neuronal degeneration including neuronophagia by histiocytic cells. The changes increase in severity, progressing from cervical to lumbar region
Thoracic cord ..	—	
Lumbar cord ..	Marked perivascular cuffing. Marked cellular infiltration of anterior horns, particularly on left side. Advanced neuronal degeneration	

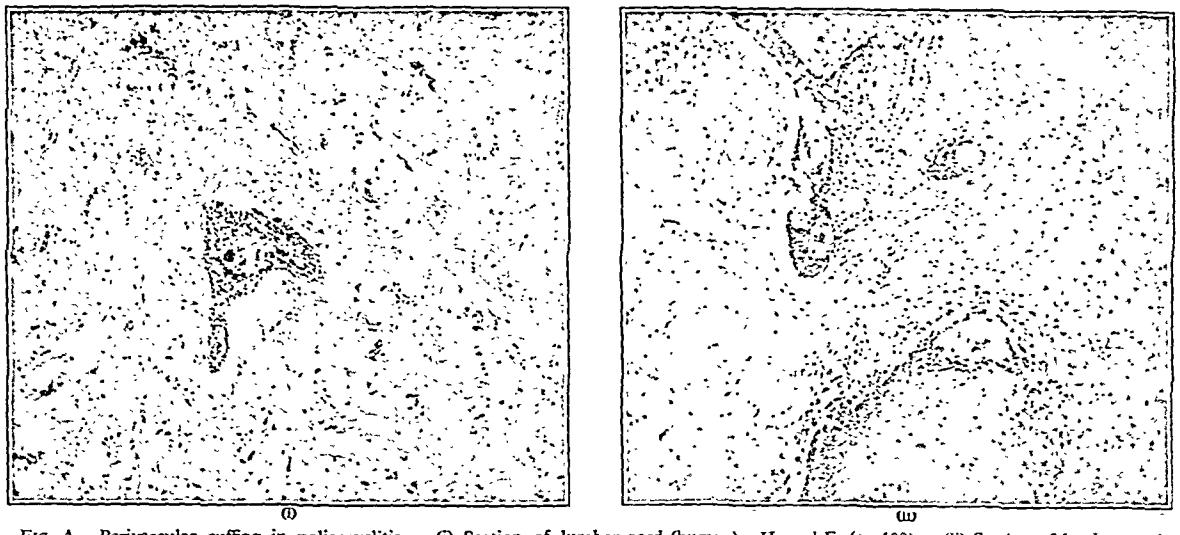

FIG. A.—Perivascular cuffing in poliomyelitis. (i) Section of lumbar cord (human). H. and E. (× 100). (ii) Section of lumbar cord (monkey). H. and E. (× 100).

The remaining organs were normal macroscopically and microscopically except for some fatty degeneration in the liver cells.

Various pieces of the nervous system were fixed in formol-saline for histological examination. Sections were stained with haematoxylin and eosin, Loyez's haematoxylin, and Mallory's phosphotungstic acid. The detailed changes noted in these tissues are shown in the accompanying Table and are compared with those of an inoculated rhesus monkey (see below) which had been similarly fixed and stained.

Animal Inoculation (Dr. F. O. MacCallum)

The diagnosis of poliomyelitis infection in this case was confirmed by animal inoculation. A suspension of pieces of cerebrum, mid-brain, and pons was prepared within a few hours of necropsy and inoculated intracerebrally and intranasally under ether anaesthesia into one monkey of the species *Cercopithecus aethiops sabaeus*. The monkey developed typical signs of poliomyelitis 13 days later and was killed with chloroform. Histological examination of the central nervous system revealed typical lesions of poliomyelitis.

A suspension of cord from this monkey was inoculated intracerebrally into a rhesus monkey, which also developed typical poliomyelitis eight days later; the microscopical lesions are well shown in Figs. A ii and B ii and in the Plate (Figs. 5 and 6). The original C.N.S. tissues of the patient were also inoculated intracerebrally into mice and guinea-pigs, with negative results.

Histological Findings

The histological changes in both the human and the monkey sections were basically the same and varied only in degree. The perivascular cuffing, neuronal degeneration, and cellular infiltration characteristic of poliomyelitis were all found in the spinal cord and brain-stem.

The neuronal degeneration (Plate, Figs. 1–6) showed itself as a loss of the nuclear membrane and of the oxyphil nucleolus (Fig. 2). Next the tigroid substance became granular or showed condensation at the side of the cell (Fig. 3). Eventually the nucleus and the tigroid substance completely disappeared, leaving a structureless eosinophil mass (Fig. 4). This was invaded by histiocytes (neuronophagia), which eventually removed it completely (Figs. 5 and 6). The cellular infiltration

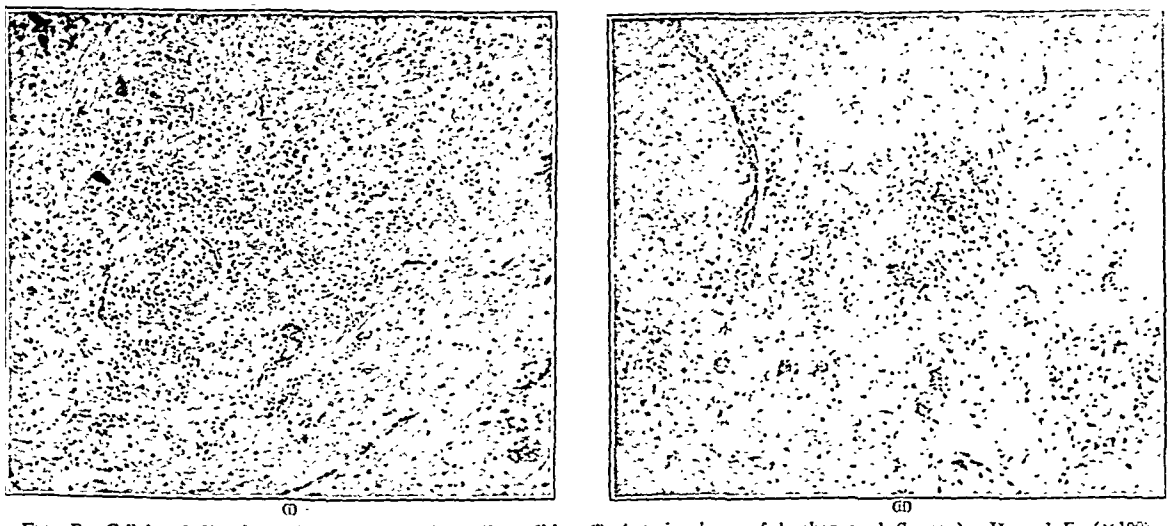

FIG. B.—Cellular infiltration of spinal cord in poliomyelitis. (i) Anterior horn of lumbar cord (human). H. and E. (×100) (ii) Anterior horn of lumbar cord (monkey). H. and E. (× 100).

of the grey matter (Figs. B i and B ii) showed the same cells as in the perivascular cuffs. No demyelination of the white matter was seen.

The perivascular cuffing (Figs. A i and A ii) consisted of an infiltration of the perivascular space with histiocytic cells and lymphocytes; very few polymorphonuclear cells were seen.

Discussion

This case of polio-encephalitis had several features of interest apart from the confirmation of the diagnosis by animal inoculation. First among them comes the encephalitic nature of the signs, the chief of these being coma and evidence of brain-stem involvement. Kelleher (1947) stated that in his experience 30% of the poliomyelitis cases seen in the first part of the 1947 epidemic were of the bulbar type; of these a few were drowsy, and one became comatose and died after being unconscious for less than 24 hours. This last case had pronounced cranial-nerve disturbances together with mid-brain and cerebellar involvement. Brewis and Neubauer (1948) described a probable case of polio-encephalitis which recovered after showing coma, fits, cerebellar signs, and spastic weakness. Laurent (1947) recounted two similar examples of encephalitis, one of which made a good recovery; the other died 16 hours after admission. Necropsy in the latter case showed only oedema in the cerebral cortex, but small areas of perivascular "cuffing" with mononuclear cells were seen throughout the brain-stem (bulb, pons, mid-brain, and basal ganglia).

These findings correspond to some extent with those in our case, in which the cortex was extremely congested but showed no other lesion. In this case perivascular cuffing was observed in the pons, particularly in its dorsal part below the floor of the fourth ventricle. In this area, too, were cells which showed peripheral concentration of Nissl's granules. Unfortunately, the medulla, cerebral peduncles, and basal ganglia were not examined, but it can be said that the changes in the pons were of a surprisingly mild order: that this was not due to the short history of the case can be seen from the intense motor-cell destruction in the spinal cord.

This sparing of the cortex has been recorded several times by investigators in the United States, including the Collective Committee investigating the New York epidemic of 1907. From their evidence and other evidence at his disposal Rothman (1931) was left in doubt about the reality of polio-encephalitis. In fact, Brown *et al.* (1948) concluded from their investigation of a large series of cases of the bulbar encephalitis type that the cerebral symptoms were in a large measure due to anoxaemia, although in a few cases focal cerebral lesions were found.

Scheinker (1947) also reported no cortical involvement, but Bodian (1947), in 24 necropsies on cases of poliomyelitis, found involvement in the motor cortex alone, usually of mild or moderate degree, in 20 instances. In this series the most severe lesions were found in the brain-stem, where the substantia nigra, the cerebellar roof nuclei, the vestibular nuclei, and the reticular formation were heavily involved. Bodian felt that stupor, disorientation, and coma resulted from these brain-stem lesions, which in some of his cases included focal softening. The series also showed almost consistent involvement of the fifth, seventh, tenth, and twelfth cranial-nerve nuclei, the seventh being slightly more involved than the others. In the cord the anterior horn cells were much more involved than those of the posterior and intermediate horn cells, and were sometimes wiped out over whole segments. These findings again correspond to those in our case.

Scheinker found a distribution of lesions in the C.N.S. comparable with those found by Bodian, the medulla, pons, mid-brain, and cerebellum all being markedly involved in his cases of poliomyelitis. He also described heavy perivascular cuffing in the substantia reticularis, in the floor of the fourth ventricle, in the periaqueductal region of the brain-stem, and in the substantia nigra. But in these regions rarely was there actual destruction of the nerve cells, and complete chromatolysis was the most advanced lesion found. Lesions in the corpus striatum, the globus pallidus, and in the hypothalamic nuclei were likewise of only moderate severity.

Scheinker found numerous foci of lymphocytes in the cranial nerves, particularly in the vagi, and also an especial concentration of cells around the vagal nuclei. Apropos of these findings he quoted the view of Sabin (1942) that the virus may spread up the vagi from the alimentary tract to the central nervous system. A simultaneous cellular inflammatory reaction, including multiplication of microglial cells and degeneration of nerve cells, was a feature of Scheinker's cases. The cellular reaction was most prominent in the medulla and mid-brain, and the cell degeneration was most pronounced in the anterior horn cells of the cord.

These main lesions of fatal poliomyelitis correspond to those in the fatal encephalitic type of case described by us. In the less severe cases which recover it is probable that the lesions are of simultaneous type and distribution but of less intensity. The extensor plantar responses in our case and the spastic paresis seen during recovery in their case by Brewis and Neubauer are evidence of a pyramidal involvement, an involvement which McAlpine (1947) has described as occurring, albeit uncommonly, in the spinal form of the disease. But it is a matter for comment that, apart from occasional motor-cortical lesions in Bodian's series, upper motor neurone lesions have not been a prominent feature to the histologist: not even pyramidal demyelination was seen in our case, and no cortical or pyramidal lesions were observed by Scheinker.

It is of course possible that the intense cortical congestion in the present case was responsible for depression of upper motor neurone function, and though cord oedema was thought of little consequence by Bodian it might be associated with the transitory Babinski responses seen in some of the spinal cases. The initial flaccidity which may be associated with these responses in some cases (e.g., that of Brewis and Neubauer) was attributed by Toomey (1940) to "cord shock," a state certainly more intangible than that of congestion or oedema. As Scheinker pointed out in describing the inflammatory response of the nervous tissues, the *whole* nervous system is invaded by the virus of poliomyelitis. It is therefore not improbable that where a pyramidal lesion occurs and recovers in a more protracted case of poliomyelitis there has been some degree of demyelination of the tracts. Such changes did not develop in our case, possibly because of its short course.

A final feature of interest is in the comparison of this case with a series of cases observed in the same district (Jennings, 1947) during the spring, summer, and autumn of 1946. These cases included eight with encephalitic symptoms (apathy, twitchings, severe drowsiness, and delirium); four with facial palsies and other cranial-nerve lesions as well as cerebral symptoms; and a number of cases, some with largely meningitic signs and symptoms, in which there were temporary Babinski responses. Although only one of these cases, and that at school, had proved contact with poliomyelitis, it now seems possible, in retrospect, that at least some of them were cases of poliomyelitis in which only the brain-stem and upper motor neurones appeared to

be involved. This likelihood was mentioned by MacAlpine 1947) after the 1947 period of poliomyelitis had included similar cases; our present case, though affording no proof, does give this concept further support.

Summary

A fatal case of infection by the virus of poliomyelitis has been described.

Although the case clinically showed a mainly encephalitic and brain-stem involvement the cerebral changes were merely those of cortical congestion, and the pons showed only a mild inflammatory reaction. The spinal cord, on the other hand, showed gross and widespread destruction of anterior horn cells. No really satisfactory histological explanation was forthcoming from either cord or brain to account for the definite clinical evidence of upper motor neurone involvement. Congestion, oedema, or very slight early changes in these neurones might be adduced as causes of the signs. Inoculation of the nervous tissues of this case in monkeys resulted in symptoms and histological lesions closely akin to those in the human subject.

This seemingly encephalitic case was thus proved to be due to an infection by poliomyelitis virus, and its features are compared briefly with those shown by possible atypical cases of the same infection seen in the same district two years previously.

Our thanks are due to Miss M. H. Shaw for the photomicrographs of the sections.

FATAL CASE OF ACUTE ENCEPHALOMYELITIS DUE TO POLIOMYELITIS VIRUS

BY

W. HOWLETT KELLEHER, M.D., D.P.H.
Physician Superintendent, Western Hospital, London

ALLEN B. BRATTON, D.S.O., M.C., M.A., M.B.
Pathologist, Central Histological Laboratory, Archway Hospital

AND

F. O. MacCALLUM, M.D.
Director, Virus Reference Laboratory, Colindale

The number of instances in which poliomyelitis virus affects the fore-brain and brain-stem seems to vary in different epidemics. Reports dealing with the 1947 epidemic in this country indicated a higher proportion than usual of cerebral and bulbar lesions with or without spinal involvement (Kelleher, 1947; McAlpine *et al.*, 1947). The picture has been confused by the occurrence, just before the poliomyelitis outbreak of 1947, of minor and localized outbreaks of virus encephalomeningitis recorded by Jennings (1947) and Laurent (1947) and regarded by them as a disease or group of diseases in which no relation to poliomyelitis was probable. On the other hand both Critchley (1948) and McAlpine *et al.* (1947) believe that the virus responsible was probably identical with that of acute poliomyelitis.

Undoubtedly the lack of facilities for the isolation and identification of virus in this country has accentuated the confusion, and, whereas Toomey (1941) recognizes eight clinical types of poliomyelitis, doubts about the existence of types other than spinal and brain-stem are held by many authorities in this country—for example, Walshe (1947), who states: "It is probable, however, that only the spinal type and a few cases of brain-stem type really belong to this [poliomyelitis] infection." Baker and his colleagues (1947), in a comprehensive review in which the word "bulbar" has been used "with some degree of licence" to denote involvement of the entire brain-stem, including the medulla, pons, and mid-brain, present an acceptable classification of all forms of bulbar poliomyelitis. They include a "diffuse encephalitic" and a "focal encephalitic" group, and, in connexion with the latter, state that aphasic disorders have been reported rather infrequently. They quote one case of visual verbal agnosia from the literature.

The following record is a description of a case of acute polio-encephalomyelitis in which during life it was not possible to make a clear clinical distinction between poliomyelitis or other virus aetiology, but in which histological evidence and ultimately virus isolation established the aetiological agent.

Case Report

A man aged 25 with a record of excellent health was admitted to the Western Hospital on Oct. 12, 1947, with a history of illness which had begun six days earlier with a sense of fatigue and malaise, followed 48 hours later by headache and giddiness. On the following day (Oct. 9) he vomited once and, because of increasing malaise and the onset of giddiness, tremors, and blurring of vision, had to take to bed. On the fourth day after the onset feverishness and thirst were pronounced. He was restless and unable to sleep, and had difficulty in hearing. His condition rapidly worsened, until on Oct. 12 he was found by his relatives to be unable to move, to be generally rigid rather than weak or flaccid, and, though conscious, to be unable to speak.

On admission at 5 p.m. on the same day he had a temperature of 101° F. (38.3° C.) and a pulse rate of 82. He was conscious, and there was some cyanosis of the extremities. He was unable to speak. A fine tremor of the outstretched hands was noted. There was moderate neck rigidity and hamstring spasm. He moved his limbs very slowly. Movements were stiff, jerky, and apparently uncoordinated, and passive movements of the limbs further revealed the general rigidity and tonic spasm. The facial muscles were involved in the general hypertonicity, and commands were obeyed incompletely and with great difficulty and delay in execution. There was fine nystagmus in all directions but most pronounced to the right. Apart from a possible weakness of the left sternomastoid muscle there were no obvious cranial-nerve palsies. All tendon reflexes were present but depressed, and the abdominal reflexes were normal. There was a doubtful Babinski sign on the right; the left plantar reflex was flexor. The respiratory muscles were unaffected and the pharynx functioned. There was no retention of urine, but he was incontinent.

A few hours later the tendon reflexes in the right lower extremity were very sluggish, but apart from the dysfunction, which was apparently due to tonic spasm, there was still no apparent paresis or paralysis; the dysarthria might also be ascribed to tonic spasm, although possibly it may have been a true motor aphasia. Lumbar puncture showed a clear fluid containing 18 lymphocytes per c.mm. and 55 mg. of protein per 100 ml.; colloidal gold test, 0111210000; Wassermann reaction negative.

On the following day (Oct. 13) there was little change, but some weakness of the right lower extremity, with greatly diminished reflexes, was noted. Consciousness appeared to be clouding and ultimately all response to stimuli failed. The tonic rigidity persisted and a fine tremor of the upper lids was

noticeable and persistent. A cinematograph record of the facies exists (Ministry of Health, 1948). A consultant neurologist made a provisional diagnosis of acute disseminated encephalomyelitis. By the next day (Oct. 14) there was marked deterioration, with a rising temperature and a tendency to accumulation of buccal secretions, but still no respiratory muscle involvement. Death, apparently due to bulbar failure, occurred rather suddenly the same evening.

Necropsy on Oct. 15 revealed a little focal haemorrhagic bronchopneumonia in the congested lungs, cloudy swelling and congestion of the liver and kidneys, and oedema and congestion of the spleen (all confirmed microscopically). The heart was normal, the air passages were clear, the pancreas and stomach were congested, and the urinary bladder was dilated. There was moderate oedema and congestion of the somewhat swollen brain and spinal cord.

Microscopical examination showed very severe perivascular "cuffing," mainly with lymphocytoid cells, and foci of acute inflammation and degeneration of parenchyma, in places almost purulent, in the basal ganglia, mid-brain, pons, and medulla—most severe in the mid-brain. The cerebral cortex in the left prefrontal, right Rolandic, and left occipital regions showed only oedema and congestion. The third and fourth cervical, fourth and eighth thoracic, and second lumbar segments of the spinal cord showed inflammation and degeneration of the grey matter, especially of the anterior horns, in which a considerable number of neurones were destroyed, and to a smaller extent of the white matter.

The findings were characteristic of acute polio-encephalomyelitis (A.B.B.).

The histological report was submitted to the consulting neurologist (Dr. T. Rowland Hill), who remarked: "A case of fulminating polio-encephalomyelitis in which, before death, it was not possible to demonstrate involvement of lower brain-stem motor nuclei. There were signs of severe mid-brain lesions in that there were tonic fits of decerebrate rigidity and marked nystagmus. There was also a degree of flaccid weakness of the right lower extremity with markedly diminished reflexes. Bulbar palsy developed before death."

Specimens of the brain and cord were stored at the Virus Reference Laboratory, Colindale, in glycerol-saline for ten months at −10° C. A 10% suspension of cord and medulla was then inoculated intracerebrally into one rhesus monkey under ether anaesthesia. The monkey developed typical signs of poliomyelitis ten days later and was killed with chloroform. Histological examination of the central nervous system showed lesions pathognomonic of poliomyelitis (F.O.MacC.).

Summary

A case is recorded of acute encephalomyelitis of clinically undetermined aetiology, in which histological findings and virus isolation established the virus of poliomyelitis as the cause.

Our thanks are due to Dr. W. H. Bradley, of the Ministry of Health, for helpful suggestions.

Hospital matrons and nurses from Belgium, Canada, Cyprus, Denmark, Egypt, Finland, France, Greece, Italy, the Netherlands, Norway, and the U.S.A. have recently attended a two weeks' course on nursing arranged by the British Council in Edinburgh. Sir Andrew Davidson, Chief Medical Officer of the Department of Health for Scotland, gave the opening lecture.

STREPTOMYCIN IN DEVELOPMENT OF HYDROCEPHALUS IN TUBERCULOUS MENINGITIS*

BY

S. N. DE, M.B., D.T.M., Ph.D.

(From the Department of Morbid Anatomy, University College Hospital Medical School, London)

[WITH PHOTOGRAVURE PLATE]

Since the introduction of streptomycin in the treatment of tuberculous meningitis several reports of hydrocephalus have appeared. Flory and his co-workers (1947) describe a case of relapse of tuberculous meningitis after cessation of streptomycin treatment in which an internal hydrocephalus was discovered at necropsy. Baggenstoss *et al.* (1947) record two fatal cases of tuberculous meningitis treated with intramuscular and subcutaneous streptomycin in which occurred heavy exudate at the base of the brain and moderate internal hydrocephalus. Wright and Rees (1948) report three cases of severe hydrocephalus associated with thick basal exudate after treatment with intramuscular and intrathecal streptomycin for at least eight weeks. Smith *et al.* (1948) describe two fatal cases with gross hydrocephalus after intramuscular, intrathecal, and intraventricular streptomycin; in two subjects who survived, ventriculography before treatment revealed some dilatation of the ventricles. In all of these cases exudate in the basal cisternae was found to be most intense.

An M.R.C. report (1948) includes 46 instances of hydrocephalus among 53 necropsies on cases of tuberculous meningitis treated with streptomycin by various routes. These studies led me, whilst interested in experimental hydrocephalus, to investigate the histological changes in the basal meninges in a small series of cases of tuberculous meningitis with the object of finding out if the administration of streptomycin had modified the lesion in any way that might lead to hydrocephalus.

Materials and Methods

The leptomeninges from the undersurface of the pons were available for histological examination from eight cases of tuberculous meningitis; six of these were hydrocephalic, two were not. Seven had been treated with intramuscular and intrathecal streptomycin, with or without intraventricular streptomycin, for periods varying from 12 to 231 days, while only one (hydrocephalic) received no antibiotic treatment. Fig. A shows the dilatation of the anterior horns of the lateral ventricles in the frontal section of the brain of a case of tuberculous meningitis treated with streptomycin.

FIG. A.—Hydrocephalus in an infant following tuberculous meningitis treated with streptomycin.

The leptomeninges, with a piece of brain tissue, were cut out from the undersurface of the pons and fixed in 10%

*Part of a thesis submitted to the University of London for the Doctorate of Philosophy.

ırmol-saline ; the planes of section of the specimens were right angles to the long axis of the brain. These were owly dehydrated and embedded in paraffin, and thin sec- ons were stained with Ehrlich's acid haematoxylin and osin as well as with Weigert's iron haematoxylin and van ieson's stain.

Results

The basal subarachnoid space in all the hydrocephalic ases were completely blocked by a fibrinous exudate and ick tuberculous granulation tissue (Plate, Figs. 1 and 2). wo of the five treated cases showed some fibroblastic roliferation within the exudate, mainly directed against ie fibrinous elements but also partly encircling some inute tubercles (Fig. 3). The other three gave no evidence f organization, nor was there any obvious histological odification of the lesions by streptomycin when com- ared with the lesions from the untreated case.

In the two non-hydrocephalic cases, both of which had een treated with streptomycin, the subarachnoid channels ere patent in spite of the presence of meningitis (Fig. 4). he fibrinous exudate and the tubercles were there, but ey were much less prominent. The lesions did not appear have been essentially modified, nor was there any vidence of fibroblastic proliferation.

In three of the hydrocephalic cases the foramina of uschka were found to be patent from the outside, and n one case histological section through this region showed he lateral recesses, including the foramina, to be nobstructed by tuberculous lesions.

Discussion

Fibrosis of the tuberculous lesions is known to be a eneral response to streptomycin treatment both in miliary ubercles in man (Flory *et al.*, 1947 ; Baggenstoss *et al.*, 947 ; M.R.C. Report, 1948) and in experimental lesions n guinea-pigs (Feldman *et al.*, 1945). This naturally roused the suspicion that streptomycin, in the course of romotion of healing of tuberculous lesions in the meninges, night lead to fibrosis and adhesions, resulting in obstruc- ion of the circulation of cerebrospinal fluid and consequent ydrocephalus.

The fact that intrathecal streptomycin had been given n many of the reported cases of hydrocephalus strengthened he view that leptomeningeal adhesions after such treat- ent were responsible for the blockage. But in the present investigation only two of the five streptomycin-treated cases showed some fibroblastic proliferation in the basal lepto- meninges, and although this reaction did surround a few tubercles it seemed to be mainly directed along the fibrin threads in the exudate. Similarly, only one of the two hydrocephalic cases of Baggenstoss *et al.* (1947) and two of 46 hydrocephalic brains of the M.R.C. report (1948) showed any fibrosis in the meningeal exudate.

Further, Rich (1944) noted the presence of some degree of organization and repair in the meningeal lesions of the more protracted cases in pre-streptomycin days. Long ago Martin (1909) recorded scar tissue as replacing antecedent tuberculous lesions in the meninges in cases that had recovered from tuberculous meningitis, while Kramer and Stein (1931) also pointed out the tendency to fibrosis of the meningeal exudate in similar cases. These facts suggest that the formation of leptomeningeal adhesions has not always been responsible for the observed hydrocephalus, nor has it been especially brought about by treatment with streptomycin.

On the other hand, one of my cases of tuberculous meningitis which was not treated with streptomycin also showed the presence of an internal hydrocephalus. A search through the older literature suggests that tuberculous meningitis by itself has long been suspected of being associated with hydrocephalus (Barther and Rilliet, quoted by Burr and McCarthy, 1900 ; Dandy and Blackfan, 1914 ; Rich, 1944 ; Martin and Elkinton, 1947 ; Bucy, 1948). Further, it has been possible to produce internal hydro- cephalus in guinea-pigs after the introduction of *Myco- bacterium tuberculosis* through the cisterna magna (De, 1949). It may therefore be concluded that tuberculous meningitis alone can give rise to hydrocephalus, and the prominence given to the condition since the introduction of streptomycin treatment is no doubt due to more careful examination of the brain in such cases.

The hydrocephalus found in association with tuberculous meningitis has mostly been of the communicating type (Wright and Rees, 1948 ; Smith *et al.*, 1948 ; M.R.C. report, 1948). In some of the brains of my series the foramina of Luschka were shown from outside to be free from any obstruction. In one case histological section confirmed this naked-eye finding. These observations support the findings of previous workers that the hydrocephalus is of the communicating type. Moreover, in all the hydro- cephalic cases, treated and untreated, the wide subarach- noid space at the undersurface of the pons had been fully occupied by a fibrinous and caseous exudate with tuber- culous granulation tissue ; there appeared to be no room left for flow of any cerebrospinal fluid. On the other hand, the two non-hydrocephalic cases presented open sub- arachnoid passages in between the scanty exudate.

I have also found that the cisternal introduction of *M tuberculosis* in guinea-pigs is followed by hydrocephalus associated with partial blockage of the cisterna pontis with considerable cellular proliferation, but in the rat this change is very slight and there is no evidence of blockage or of hydrocephalus (De, 1949). These facts also suggest that internal hydrocephalus in tuberculous meningitis is due to and occurs with obstruction of the basal subarachnoid by the tuberculous exudate, independent of any streptomycin treatment.

It should be noted in passing that in most of the present cases with streptomycin treatment the tuberculous lesions elsewhere in the body have shown some modification in the form of increase of collagen, and in one case almost complete replacement by lymphocytes. But in spite of the intrathecal administration the meningeal lesions failed to respond. Of course, in the two non-hydrocephalic cases the basal exudate was less intense, but it is difficult to decide if this is an effect of streptomycin, especially in the absence of any essential change in the histology. It is interesting to recall that the M R.C. report (1948) recorded a similar finding in relation to the meningeal lesions where the fibrinous exudate around the lesions was suspected to shelter the bacilli from the effect of the antibiotic. Hinshaw and Feldman (1944), the originators of strepto- mycin therapy in tuberculosis, also realized that patho- logical characteristics of the local lesions can impose marked limitations in the treatment of clinical tuberculosis.

Conclusions

Tuberculous meningitis can give rise to an internal hydrocephalus associated with complete blockage of the cisterna pontis by tuberculous granulation tissue and a copious fibrinous exudate, but independent of the develop- ment of cisternal fibrosis. There is no convincing evidence that streptomycin increases the chance of this complication by stimulating the production of reparative tissue.

I wish to thank Professor G. R. Cameron, F.R.S., for his help in the preparation of this paper, and Mr. McDonald for the photomicrographs reproduced in the photogravure plate.

Medical Memoranda

Paraffin-wax in the Male Bladder

The following case of a foreign body in the bladder, and the method of evacuating it, may be of interest.

CASE REPORT

One evening a young man, acting under an obsessive compulsive urge, fashioned a bougie, about 2½ in. (6.25 cm.) long by about ¼ in. (0.6 cm.) in diameter, out of candle droppings and passed it up his urethra, from whence it slipped into his bladder. The next morning he came to hospital complaining of pain and frequency and giving the above history. Cystoscopy showed the bougie, broken into three fragments, as three white rods floating in the water used for distending the bladder. A Braasch direct cystoscope was passed and efforts were made to grasp the fragments with a Bumpus specimen-taker. These efforts were unsuccessful, because the paraffin rods, floating at the top of the bladder, eluded capture by bobbing away. As the paraffin-wax from which this candle was made was capable of solution by liquid paraffin of medicinal quality of a specific gravity of 850 at a temperature of 120° F. (48.88° C.), it was decided to try dissolving the bougie. A piece of candle ¾ in. (1.9 cm.) long could be dissolved in 20 minutes, and it was hoped that solution of the bougie would be effected by washing out the bladder for an hour with the liquid paraffin at a temperature of 120° F. The bladder was accordingly filled with the specified liquid paraffin and emptied at two-minute intervals, 2 oz. (57 ml.) of the oil at 120° F. being used for each filling. The washings from the bladder undoubtedly contained fine particles of wax, but cystoscopy immediately afterwards showed no appreciable difference in the size of the rods. The possibility of melting them by using short-wave diathermy was inquired into, but as the elevation of temperature would not exceed 5° F. (2.8° C.) above blood heat the idea was abandoned.

In 1924 Wardill, of Newcastle, described a technique for cystoscopy using liquid paraffin as a medium instead of water. The wax from which the bougie was made sank in liquid paraffin of a specific gravity of 850, and by using liquid paraffin instead of water and thus having the fragments of the bougie lying on the trigone instead of floating near the fundus it was hoped that the Braasch cystoscope and Bumpus specimen-taker, so useful in the extraction of foreign bodies heavier than water—stones, etc.—might do the trick. However, we met with failure again, because air bubbles, which the bubble extractor of the Braasch cystoscope could not expel, prevented visualization and the bougies were not even glimpsed.

As a last resort, 4–5 oz. (114–132 ml.) of liquid paraffin of a specific gravity of 850 was instilled into the bladder and the patient was asked to void. It was hoped that this manœuvre, by bringing the fragments of the bougie more on a level with the internal urinary orifice, might effect their evacuation. At the first filling one fragment of the bougie came away, and at a subsequent filling, a couple of days later, the remaining fragments were voided. Doubtless the lubricating effect of the liquid paraffin played some small part in helping their expulsion. The above operations were carried out under penicillin-sulphonamide cover.

It is quite possible that the use of liquid paraffin of low specific gravity, as described above, may prove helpful in securing the evacuation of other lighter-than-water foreign bodies not too large to be voided. The method seems so innocuous that it is worth a trial, and information regarding such trials would be very welcome.

It is obvious that it would be simplicity itself to remove these fragments by cystotomy, but it seemed a pity to do this if it could be effected otherwise.

It is a pleasure to acknowledge help from Dr. R. Collis, Dr Norman Moore, Mr. Albert le Brocquy, of the Greenmount Oil Co., Dublin, Dr. Dacre Hamilton, of Dublin University Medical School, and Mr. Morris, of the Irish Electro-Medical Co.

Histamine Desensitization in Ménière's Disease

The following case of moderately severe Ménière's disease responded so well to treatment by histamine desensitization that it is considered worth recording. This form of treatment in histamine-sensitive patients is most strongly recommended, as there is little doubt that it achieved success in this case. The result also supports the findings and experience of Miles Atkinson and others who have obtained success in the great majority of their cases.

CASE REPORT

The patient, a high-ranking officer in the Royal Air Force, was posted abroad in November, 1946, to take command of a very important air-training project. Shortly after his arrival I was called one night to see him, as he was suffering from a sudden attack of intense vertigo, with nausea and vomiting, tinnitus, and deafness.

I arrived to find him quite prostrate, with extreme pallor, and covered with clammy sweat. He was vomiting repeatedly and complained of pronounced giddiness except in the prone position. His pulse was very rapid and barely palpable. There appeared to be a momentary loss of consciousness. I could not detect nystagmus, though this sign was evident in subsequent attacks. The cardiovascular, respiratory, and central nervous systems were clinically normal and I could find no evidence of focal sepsis. Little doubt remained that this was a case of Ménière's disease—a diagnosis supported by his previous history.

His wife informed me that he had suffered two previous attacks in England, the first some months previously and the second shortly before he left the United Kingdom. He had been seen then by two specialists, both of whom had confirmed a diagnosis of Ménière's disease. He had been taking 2 gr. (0.13 g.) of phenobarbitone twice daily for several months and had been given the usual instructions regarding reduced salt and fluid intake. I prescribed bromides and hyoscine which gave some relief, but his attack continued practically throughout the night. He had completely recovered in 48 hours but stated that his hearing was still somewhat impaired and that tinnitus was troublesome. It was known that he had

been suffering from a high-tone deafness for many years, and the impairment of hearing was therefore not altogether related to Ménière's disease. Exactly a fortnight later I was again called out in the early hours and found him in a precisely similar attack, from which complete recovery occurred again within two days. The attacks continued at roughly two-weekly intervals, a total of six being recorded.

In January, 1947, some two months after his arrival overseas, when I had attended him in five attacks, I was faced with the problem of deciding whether this valuable officer could remain abroad or whether I should have to invalid him. He had been specially selected for this post because of his wide experience, and he was naturally most anxious to fulfil his mission. I discussed his case with several colleagues, including an E.N.T. consultant. As a result of these discussions and information obtained from current literature—e.g., Atkinson, M., *Proc. R. Soc. Med.*, 1946, 39, 807—a skin test was carried out in order to determine whether he was histamine-positive or histamine-negative. The test is fully described in the "Any Questions?" section of the *British Medical Journal* of May 10, 1947 (p. 666), and is of course an essential preliminary to treatment if histamine desensitization is contemplated. The patient proved to be a well-marked example of the histamine-sensitive group, and I decided that he might well benefit from a desensitizing course of histamine. This treatment is also described in the section of the *B.M.J.* quoted above.

The sixth attack since his arrival developed in the early stages of treatment, which was begun in January, 1947, but was notably less severe than those from which he had previously suffered. The course was completed in April, 1947, since when (apart from mild tinnitus), he has been in excellent health and completely free from further attacks. There has also been subjective improvement in his hearing. It should be mentioned here that he has had no phenobarbitone or other medication for the past 12 months.

As more than two years has elapsed since this treatment was first given, it is reasonable to assume that a cure has probably been effected; in any case, a remarkable response has been demonstrated to histamine desensitization. Several skin tests carried out since this time have shown a consistently negative reaction.

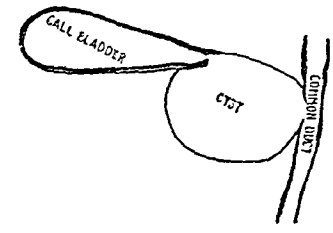
A point of interest is that the patient's flying category, which was reduced in 1946 to non-combatant flying (passenger only), has been restored to that of an active pilot category, and he has been able to carry on with an arduous and intricate task at a highly responsible level with the utmost confidence and efficiency.

I wish to thank the Director-General of R.A.F. Medical Services and the patient for permission to publish this case

SAVILLE PAUL, M.R.C.S., L.R.C.P.,
Principal Medical Officer, R.A.F., Southern Rhodesia.

Congenital Cyst of the Cystic Duct Containing Calculi

I have been unable to find a report of a cyst of the cystic duct; it may be of interest, therefore, to record a case that has been under my care recently.



CASE HISTORY

A married woman aged 56 was referred to me on account of attacks of upper abdominal pain and vomiting for two years. During the attacks some tenderness had been elicited over the gall-bladder region. There had been no previous illness, but during this period she had had discomfort after eating, with flatulence, and had gained considerably in weight. There had never been any jaundice. The attacks of colic and vomiting had coincided, and the vomit was either green or brown. She had never been pregnant, and the menopause occurred at age 50.

The patient was very obese and thick-set, but otherwise quite healthy-looking. The tongue was clean, the pulse regular 108 a minute, and the blood pressure 110/65 mm. Hg. No physical signs were detected except some haemorrhoids. During chemical and radiographic investigations (during which the only abnormality noted was a group of five ring shadows medial to and a little below the shadow of a gall-bladder which emptied normally) the patient had two further attacks of colic, and after one of these I detected a definite tenderness below the right costal margin. In view of the severity of the attacks an exploration of the biliary passages was carried out.

Operation.—A general anaesthetic consisting of hexobarbitone, gas, oxygen, and ether by intubation was administered by Dr. E. S. M. Merry. A transverse incision was employed, but owing to the patient's obesity, the flatulence, and the high gall-bladder the incision had to be extended upwards through the rectus sheath to get the necessary exposure. The gall-bladder was partially enclosed in a tunnel of liver substance. Its fundus protruded through the anterior surface of the liver. The organ was distended with bile but did not look unhealthy; but medial to its neck a hard mass could be felt deeply buried in fat which also contained the common bile duct. On dissection of the mass the common bile duct was seen to be of normal size and free of calculi.

The hard mass was in the situation of the cystic duct and consisted of a thin-walled cyst packed tightly with calculi and biliary mud. On traction on the neck of the gall-bladder it was seen to be in continuity with the cyst (see Fig.). In an attempt to bring the parts nearer to the surface the gall-bladder was dissected from the liver, but immediately it was pulled on gently it tore away from the cyst, with which it communicated by a small aperture. This was enlarged and the contents of the cyst evacuated—

the mud by suction and five black pigment calculi the size of small peas by forceps. The walls of the cyst, which was the size of a hen's egg, were extremely thin and translucent. In view of the difficulty anticipated in removing it a tube was passed into the common duct through the cyst cavity and the size of the cyst reduced by plicating sutures. The gall-bladder bed was then peritonized and the wound closed.

Examination of the gall-bladder after its removal revealed cholesterosis and three calculi similar to those in the cyst itself. As the wall of the gall-bladder was at least of normal thickness and that of the cyst was thin, translucent, and devoid of fibrous tissue and muscle, I consider that the cyst was of congenital origin and not part of an hour-glass gall-bladder. There was no inflammation, and the symptoms seemed to have arisen mechanically when its fluid contents had been replaced by the mud and calculi. These appeared to fill its cavity, but the cholecystogram showed that a passage for bile still existed between the common duct and the gall-bladder through the cyst itself. No trace of a cystic duct was seen, and the opening from the cyst into the common duct was large enough to take a No. 10 catheter easily.

COMMENT

I believe that the absence of biliary mud from the gall-bladder and common duct and its presence in the cyst was due to the flow of bile carrying into the duodenum any that escaped into the common duct during attacks of colic, and that the weight of the cyst caused valve-like actions at its junctions with the common duct and gall-bladder.

I am indebted to Professor Paterson Ross for his helpful comments in presenting this case for publication.

DOUGLAS S. PRACY, F.R.C.S.Ed.,
Honorary Surgeon, Nuneaton General Hospital.

The *Manchester Guardian* (June 30) has reported that the Bath Education Committee has had to close the city's school dental service because of lack of professional staff. The result of this will be that 8,000 school-children will be deprived of regular dental inspection.

Reviews

DEVELOPMENT OF HOSPITALS

Hospital Trends and Developments 1940–1946. Edited by Arthur C. Bachmeyer, M.D., and Gerhard Hartman, Ph.D. (Pp. 819. $5.50 or £1 10s.) New York: The Commonwealth Fund. London: Geoffrey Cumberlege. 1948.

There are more than 160 contributors to this work; a few of them, including the late Lord Dawson and Sir Frederick Menzies, are British. It is a collection from the literature made to facilitate reference by those whose work is in this field—administrators, heads of departments, and students of hospital administration. Readers of the *Journal* will note with pleasure that Lord Dawson's contribution appeared originally as a leading article (May 9, 1942, p. 573), though its form here is taken from another source. Despite the unavoidable divergences from existing conditions due to its date, there could hardly be a more informative or more stimulating contribution for readers on this side of the Atlantic. There are approving commentaries upon the article by a number of leading authorities in the U.S.A. How necessary it is to think along similar lines there may be inferred from such a sentence as this, from J. S. Falk's contribution: " . . . In most urban areas and in nearly all rural areas poverty and lack of medical care go along together." All the articles upon current trends make it obvious that in the United States opinion is veering towards a plan like our own in almost every particular, and it looks as if President Truman's recommendation to Congress for a national service may find a great deal of informed support.

Turning the pages, one finds a contribution by J. A. Hamilton with headings such as these: Haphazard Location of Hospitals; Improper Construction; Poor Distribution of Skilled Personnel; Lack of Integration of Health Agencies; Lack of Trained Management; High Cost of Hospital Care; Lack of Co-ordinated Co-operation; Conduct of Regional Surveys; Establishment of Voluntary Regional Councils; Development of Group Practice; The Health Centre; and so on. They might have been taken direct from our surveys and the commentaries upon them. Article after article repeats their substance.

Part II of the book considers administrative problems. The American machinery differs from ours, and the discussion is in parts more theoretical and academic than is customary here.

Part III concerns departments. In the section on nursing there is to be found the sentence: " . . . It would seem economically sound for hospitals to consider using both professional and practical nurses." Despite the rather unkind and no doubt unintentional antithesis, it is notable that the distinction should be made between those to whom the doctors look for technical assistance and those to whom the patient looks for personal comfort, bodily and mental—a fundamental division of function, imperfectly realized. The bibliography does not include the reports on nursing produced here. The section on the operating theatre contains a chapter on electrical hazards which it would be opportune to study in this country. There is scarcely one article in this part from which it would not be possible to cull some illuminating remark.

Part IV deals with the finance, design, and servicing of hospitals; Part V with public health, health insurance, and regional planning.

The editors have done an excellent piece of work, and their book is a worthy successor to two already well known: *The Hospital in Modern Society*, and *Hospital Care in the United States*.

E. ROCK CARLING.

RHEUMATISM IN CHILDREN

Juvenile Rheumatism. By G. E. M. Scott, M.B.(Melb.), L.R.C.P.Ed., L.R.F.P.S.(Glasg.). (Pp. 163. £1 5s.) Melbourne: W. Ramsay (Surg.) Pty., Ltd. 1948.

In the present state of our knowledge of acute rheumatism information on the incidence, severity, and general clinical picture of this condition in different parts of the world is much to be desired. A monograph on the disease from Australia should thus be of considerable interest.

This handsomely produced book represents the clinical impressions of acute rheumatism in childhood formed by the author while an assistant medical officer in the Rheumatic Clinic of the Children's Hospital, Melbourne. The majority of the chapters consist almost entirely of a review of some of the current literature on the subject. Unfortunately, no new data are provided on the incidence, aetiology, or pathology, and the social aspects of the disease appear to be almost completely neglected. The chapters dealing with the clinical features are profusely illustrated with detailed reports of some of the 645 cases personally observed by the author. These confirm the already well-known fact that there is little difference in the clinical picture of acute rheumatism as seen in Australia from that observed in the northern hemisphere. Although it sets forth the author's personal views, the book unfortunately adds nothing to our knowledge of this baffling disease.

C. BRUCE PERRY.

DISEASES OF THE CHEST

A Practical Manual of Diseases of the Chest. By Maurice Davidson, M.A., M.D., F.R.C.P. Third edition. Oxford Medical Publications. (Pp. 670; 268 figures. £2 10s.) London: Geoffrey Cumberlege (Oxford University Press). 1948.

In the third edition of his well-known textbook Dr. Davidson has made a number of additions and revisions. Certain of the reproductions of radiographs have been replaced by more satisfactory ones. The basic plan of the book, however, remains unchanged. Its object is to present a readable and practical account of current practice in chest diseases. Case reports from the author's life-long experience are added in the text to illustrate practical points. There is at the end of each chapter an adequate list of references, both to more detailed textbooks on special subjects and to original papers.

Dr. Davidson's literary style is leisurely, and brings with it a reminder of more spacious days. The younger physician will find described here certain methods which he may think out-moded—for instance, the creosote chamber in bronchiectasis, and the use of atropine for pulmonary oedema. While the emphasis of the book is on practical aspects, space is not always allocated in accordance with the importance and frequency of diseases in practice; the section on asthma, for example, consists of only 22 pages out of the 660 which the volume contains. It is unfortunate that in the section on bronchiectasis the diagrams and nomenclature of bronchial anatomy published by Nelson in 1934 are reproduced, whereas in a note on the anatomy of the bronchial tree and in the section on bronchography, which has been revised with very helpful line-drawings to clarify the illustrative bronchograms, the later anatomical nomenclature of Foster-Carter and Hoyle is used.

These are minor criticisms. On the whole the book can be recommended as a reliable account of chest disease which will rarely fail to give the physician some indication of what to do when faced with practical clinical problems.

J. G. SCADDING.

MEDICINE IN THE SHETLANDS

A Shetland Parish Doctor. By Harry Pearson Taylor, J.P., M.B., C.M.(Aberd.). With foreword by T. E. Saxby, J.P., F.R.F.P.S., L.R.C.P.&S.Ed. (Pp. 136; illustrated. 10s. 6d.) Shetland: T. & J. Manson (Shetland News Office, Lerwick). 1948.

It was a lucky day for Shetland in June, 1890, when Dr. H. P. Taylor was appointed parish medical officer for the islands of Yell and Fetlar, for the job and the man fitted one another like hand and glove. One would hardly have expected it, for Taylor was born in Yorkshire, received his early education in Northumberland, and had nothing Scottish about him except his training at Aberdeen University. He had gone to the place as a locum to a sick man and had no intention of remaining,

but he spent the rest of his life there, rarely leaving the island. As he says, he fell in love with the place and never wished to leave it, in spite of temptations to do so. It certainly was not the salary which tempted him—£55 a year for Yell and £15 for Fetlar—with what he could pick up in the way of private practice among a mostly poor and hard-working population.

He had to tackle everything, generally single-handed, for his nearest medical neighbour was on another island and communications were often very difficult. But Taylor was essentially a handy man, and very bravely and ingeniously he dealt with many cases which in town life would have been sent to hospital. He had a flair for mechanics, which was sometimes exercised on the engines of ships coming to the island. He and his wife built a reflecting telescope from which they derived much pleasure.

Anyone who is inclined to patronize the "mere country doctor" would get a surprise if he read this book. There is not an atom of self-pity in it, but the long walks (at first all was done on foot or by means of a boat) in desperate weather over rough country must have been trying, and there was never any question of sending the case to another doctor. For 35 years Taylor was the doctor and friend of everybody on the two islands, and it is good to learn from a foreword by the publishers that he was appreciated and loved by everybody.

The doctors in the Highlands and Islands have always had a strenuous job—one which could appeal only to men who are country-lovers and "doctors by the grace of God." Taylor tells how much the coming of the Highland and Islands Medical Service meant to him and his colleagues in the improvement of their conditions.

There are many racy stories about the people and their customs, some of which disappeared during Dr. Taylor's time. I have no doubt the book will be treasured by many Shetlanders both resident and exiled. I sincerely hope it will have a wide circulation among people who have never seen Shetland but would like to know something about it and its people. They will be well rewarded by the tale of the life of a fine character. As for myself, the story left me with a regret that I never met Dr. Taylor. He was a credit to our profession.

The book is finely illustrated by pen-and-ink sketches and some colour plates, all the work of the author, who was evidently no mean artist.

ALFRED COX.

ABNORMAL PSYCHOLOGY

Abnormal Psychology. By James D. Page. (Pp. 441; 15 figures. $4.00 or £1.) New York and London: McGraw-Hill Book Company, Inc. 1947.

Here at last is a book properly proportioned to the needs of the doctor who sees patients outside a mental hospital, whether in general practice or in the wards and out-patient department of a general hospital. The psychoses are clearly and adequately described, but they do not dominate the book. More attention might have been paid to psychosomatic conditions and the visceral neuroses if this appeal to the profession outside the ranks of the specialist psychiatrist were to be fully met, but little complaint can be directed to either the matter or the manner of the book. It is clear, concise, and well balanced.

The author gives the impression of basing his statements throughout on a close and reasoned study of facts and figures, yet he has entirely avoided a dry statistical style. It is interesting to note how doctrines which twenty years ago seemed speculative and theoretical have stood the test of practical investigation and, at least in this book, appear as well-authenticated propositions in established psychopathology.

The opening chapters give a clear picture of the differences between normal and abnormal, of motivation and adjustment, mental mechanisms and symptoms, and the general causes of abnormal behaviour. In the rest of the book the sections on the psychoneuroses, alcohol, epilepsy, and crime are specially to be commended. The profession as a whole should do their best to read this excellent book—even surgeons would benefit by its perusal.

Hamlet and Oedipus. By E. Jones, M.D., F.R.C.P. (Pp. 160. 12s. 6d.) London: Victor Gollancz. 1949.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JULY 23 1949

THE GRADING OF SPECIALISTS

The results of the grading of specialists have caused great dissatisfaction in all parts of the country. Much of this dissatisfaction is due to the fact that the Assessment Committees in the various regions interpret their duties differently. Thus, in one region the criteria for grading are, to the outside observer, far stricter than those in an adjacent region. This inequality naturally causes sharp resentment and a feeling of injustice. As our correspondence columns show, some men blame the Ministry of Health for this, while others suggest that the B.M.A. or the Joint Committee should act to put matters right. It is therefore, in the first place, important to make it clear with whom the responsibility for grading lies.

In November, 1948, the Ministry of Health requested Boards of Governors and Regional Boards to set up Assessment Committees for the purpose of grading. An Assessment Committee consists of seven members: two general physicians, two general surgeons, one obstetrician, and two specialists in the branch of medicine practised by the doctor to be graded; of the two specialists one is to be nominated by the university in the region. The first five of these must have practised or be practising in the area of the Board. They are chosen for "their high professional standing and wide clinical experience and their knowledge of the Services of the area." The first point, then, is that the grading is done by the profession itself, not by the Ministry of Health, not by the Royal Colleges, and not by the B.M.A.

In its circular the Ministry of Health gave the Assessment Committees general guidance. It was stated that no general criterion of specialist status could be laid down: "a proper assessment can be arrived at only after a consideration by professional advisers of the *qualifications and experience* of each practitioner" (our italics). The circular made it clear that in many instances specialist status could be decided easily on the basis of academic qualifications backed up by experience and practice as a consultant. In the case, for example, of the general-practitioner specialist it was stressed that status could not depend solely on the possession of postgraduate qualifications: the determination of status "must take account of experience, which may of itself suffice to warrant acceptance as a specialist." It does not seem that the Ministry of Health could have given general guidance in any other terms. The guidance is based on the situation that exists. Any suggestion that grading should be done by some central mechanism would, we feel sure, be resented by the medical profession. Clearly the decision must lie in the hands of the men on the spot in the regions. That Assessment Committees in different regions will interpret their duties differently seems to be inevitable; it is equally inevitable that comparison of the results in adjacent regions will cause dissatisfaction. One way of removing dissatisfaction is to establish a system of appeal that will appear fair to the man who considers that he has not been properly graded. The appeal mechanism is now the Assessment Committee with two additional members appointed to it. The practitioner appearing before such an appeal committee may feel that it is weighted against him, and it would seem fair, therefore, if at least half of the members of the Appeal Committee were to come to the hearing of the case with unbiased minds.

There is much to be said for the suggestion that in the future it is the posts that should be graded. Only those men should be appointed to such posts who fulfil the necessary criteria; and if suitable candidates cannot be found such posts should not be filled. In this way we should be able to cut across the undesirable practice of some regions of attempting to fill specialist posts with men graded as senior hospital medical officers—an attempt to avoid responsibility for making proper payment for work done. One of the problems now is to find jobs for men of registrar status, men, that is to say, who have taken higher qualifications, have had experience as specialists, and who have been qualified for four or five years. As a result of the war it has not been possible for them to find their way gradually into specialist and consultant work, and it is a commonplace that when a hospital vacancy is advertised there is for any one post a large number of suitable applicants. This applies especially to posts for general physicians and general surgeons. It is therefore difficult to believe that, with the exception of a few specialties, there is such a dearth of suitable candidates as to excuse the financial subterfuge of trying to fill posts with senior hospital medical officers. One of the aims of the new hospital service is to see that there is available in all parts of the country adequate consultant and specialist skill. That there has been an undue concentration of such skill in large cities to which teaching schools are attached is admitted. The hospitals in the small towns have to a varying extent been staffed by men who would be unlikely to be appointed to the

staff of a teaching hospital. But these men, many of them coming under the designation of general-practitioner consultant, have secured the confidence of the local medical profession and the local community as surgeons and as consultant physicians. In time it may be assumed that when they retire their place will be taken by men and women who practise entirely as consultants or specialists, many of them, it may be hoped, recruited from outstanding general practitioners in the district. In the transitional period, which may last for years, it would be unjust to attempt to degrade such men from the positions they have hitherto held. In so far as they practise as consultants and specialists they should be remunerated as such.

It must be remembered that the Spens Committee emphasized that all specialists should be treated equally, those of outstanding ability to have their services recognized by Distinction Awards. The Ministry of Health circular made it plain that hard-and-fast criteria cannot be laid down for specialist status. What is needed is an exact definition of senior hospital medical officer. The B.M.A. is resisting all attempts to include under this category those judged on the basis of either qualification or experience to have specialist status. It is doing this by refusing to advertise in the *Journal* posts for S.H.M.O.s required to do specialist work. The Ministry of Health will not make new appointments in the grade of S.H.M.O. except within a field agreed with the Joint Committee. Nevertheless, there would seem to be a case for the grade of S.H.M.O. in mental hospitals, tuberculosis sanatoria, and fever hospitals. Could it be said, for example, that an assistant medical officer in an isolation hospital should be designated as specialist and be paid in the terms of the Spens Report? The same question may also be asked of men similarly placed in sanatoria and mental hospitals.

Government spokesmen have stressed the need for more specialists and consultants and for these to be distributed more evenly throughout the country, so that the public taking advantage of the National Health Service may have equal opportunities of obtaining specialist advice and skill. Yet young men with the necessary qualifications and experience are now finding it extremely difficult to get work to enable them adequately to support themselves and their families. Other men who have been doing such work to the satisfaction of their colleagues and the local community are being financially penalized by the decisions of Assessment Committees. This unsatisfactory situation presents a challenge both to the medical profession and to the Ministry of Health. If a solution of the problem is not soon found the public will have the right to ask why they are not being given the medical benefits promised them between 1945 and July 4, 1948.

NEW PROBLEMS OF RHEUMATISM

Study of the rheumatic diseases has been discouraging to both clinician and research worker because of the lack of pathological knowledge and the absence of proved methods of treatment, but the recent work by Kendall, Hench, Slocumb, and Polley at the Mayo Clinic, to which we have already referred,[1] has dramatically widened the field in the treatment of the rheumatic group of diseases. Those who have seen the results of the treatment of rheumatoid arthritis with "cortisone" have been left in no doubt about its efficacy. In the light of this recent American research many of the different types of rheumatic disease must be regarded from a new viewpoint, and in this issue of the *Journal* there are four papers on various aspects of the subject. Dr. Bernard Schlesinger points out the importance of studying rheumatoid arthritis in the young, in whom the condition appears, as Still's disease, in its most acute and uncomplicated form. In these cases the adenopathy, splenomegaly, and fever are more marked than in adults. If the suprarenal glands are at fault in this disease, as the new work suggests, it may be that in children the rest of the endocrine system reacts by over-production: in the case of the pituitary this might, for instance, account for the labial hirsuties and possibly other unexplained phenomena. There may also be a connexion between the pituitary and the incidence of leucopenia and, particularly, lymphopenia. It has been shown that the 11- and the 11-17-oxysteroids have some control over the lymphoid tissue, and the effect of ACTH (adrenocorticotropic hormone) can be measured by the drop in circulating eosinophils and lymphocytes.[2] As Schlesinger states, further research into the blood changes in this disease is required. In the twenty cases of Still's disease which he reports four developed jaundice, and in one of these the rheumatoid arthritis vanished. It will be recalled that the recognition by Hench of the fact that jaundice induced remissions in adult rheumatoid arthritis was one of the steps which led him to the final attack on the disease with cortisone.

Some physicians have considered that rheumatoid arthritis is a psychological disorder. The results of clinical tests with cortisone, during which any possible psychological effect was carefully eliminated by giving control substances for certain periods—with relapse in each instance—has disproved this theory. The fact that shock may precipitate the onset of this disease is significant in the light of Selye's[3] work on suprarenal exhaustion and the onset of "stress" diseases. How-

[1] *British Medical Journal*, 1949, 1, 812, and 2, 24.

[4] *Ibid.*, 1946, 24, 808.
[5] *Ann. rheum. Dis.*, 1949, 8, 90.

ever, though rheumatoid arthritis is not a psychological disorder, there is no doubt that in treating rheumatic diseases the clinician will encounter cases which can be described, in a term coined by Hench and Boland,[4] as psychogenic rheumatism. They reported that 16–18% of the patients in U.S. Service hospitals devoted to the treatment of rheumatic diseases were suffering from musculo-skeletal psychoneuroses. A careful study, with controls, of this condition is now reported by Drs. William Tegner, Desmond O'Neill, and Anna Kaldegg. They point out that in such cases the patients described their pain in unusual terms; it was widespread, and might be represented as "pain all over." The distribution of the physical findings, which were inconstant in site, did not correspond to any recognized physical disorder. These authors confirm the American view that analgesics have no effect on the symptoms, but differed in their findings that cold and damp affected both patients and controls equally. Now that psychogenic rheumatism is recognized as an entity, diagnosis should not be difficult, for the history is bizarre and the findings are unrelated to organic disease. It is important that the correct diagnosis should be made, because such patients do not require physiotherapy, which will only perpetuate their symptoms. Some method such as group psychotherapy might be tried.

Rheumatoid arthritis is of course the most crippling but not the most common form of rheumatic disease. The majority of patients attending the rheumatism department of a hospital come with conditions which can be classified under the heading of non-articular rheumatism or fibrositis. Many clinicians deride such a diagnosis, and workers in the U.S.A. tend to disregard it. But the fact remains, as any general practitioner will confirm, that this condition forms the bulk of "rheumatism." In a paper also published in this issue Dr. W. S. C. Copeman describes research work he has undertaken on the relation of fibro-fatty tissue to "rheumatic" syndromes. Certain important facts about the anatomy and physiology of this little-studied part of the body have come to light. The discovery of the fatty herniae and the oedematous changes found in the fatty tissue in certain sites should be considered in relation to the new knowledge about the connexion between the rheumatic group of diseases and the suprarenal cortex. Of the twenty-eight steroids so far isolated from the suprarenal cortex only six are known to be active, and of these desoxycorticosterone has been studied in more detail than the others, particularly in relation to Addison's disease. It is largely concerned with electrolyte balance, and in Addison's disease there is increased excretion of sodium and chlorides and retention of potassium. This may cause increased intracellular fluid tension. Copeman points out that in the dorsal and sacral fat-pads, and in similar pads round the knees and ankle where fibrositis occurs, this may be due to oedematous distension of fat owing to an upset of the water balance. He suggests there may be an endocrine cause, and the new work strengthens this concept.

Leading rheumatologists have for years insisted that diagnosis must be more accurate if progress is to be made in the treatment of rheumatic conditions. Hench[5] emphasized last year in a lecture given in this country the breadth and complexity of the work in this field, and he pointed out that there are about a hundred different types of arthritis and another hundred musculo-skeletal conditions called "rheumatism." In spite of the recent success of the Mayo Clinic workers with cortisone, many more careful studies, on the lines of those reported in this issue, must be made before the outstanding problems still presented by the rheumatic group of diseases can be solved.

MOSQUITO ERADICATION

The object of mosquito eradication is the total destruction of one or more species in a defined area within limited time, the area being chosen in such a way that reinvasion is unlikely, or can be easily avoided, and work can be stopped on attainment of the object. It is therefore in the nature of capital expenditure, in contrast to the normal recurring expenditure on mosquito control. Mosquito eradication originates from techniques developed by the Rockefeller Foundation as long ago as 1928 for the destruction of *Aëdes aegypti* in the control of yellow fever. The means then used were destruction of *Aëdes* larvae by normal methods, such as the application of larvicides and the removal of breeding-places, the establishment of a thorough checking system (using the search for adult *Aëdes* as an index of effective larval destruction), and the perfection of anti-larval measures where they were shown to be inadequate by the continued presence of even single adults. This system achieved such success against the essentially urban *Aëdes* in South America that it was rapidly extended over most of the continent, and now that mosquito has been eradicated from a large part of South and Central America.

The first application of this principle to anophelines was made in 1939, when it was found that *Anopheles gambiae*, the main malaria vector of tropical Africa, had

gained entry into Brazil, and after seven or eight years silent multiplication had started devastating epidemics of malaria in the country around Natal. An eradication scheme was begun by the Brazilian Government with the help of the Rockefeller Foundation.[1] It was based on the same principles—Paris green was used as a larvicide, and an elaborate checking system based on the search for adults was instituted. Within 22 months of starting this work total eradication had been achieved. Success was demonstrated by the only effective test—the cessation of all anti-larval work with the maintenance of the checking system over a period of at least one year. This scheme covered an area of roughly 5,000 sq. miles and cost $2,140,000. Though the cost was high, it was considered small in comparison with the damage *Anopheles gambiae* had been causing.

The second campaign against anophelines was carried out under almost identical conditions in Egypt during 1944–5. Overwhelming epidemics of malaria in 1942 and 1943 in the 300-km. stretch of the Nile valley south of Assiut proved to be due to *Anopheles gambiae* —a stranger to Egypt which had gained entry at some recent time. The eradication scheme was started in 1944 with the help of the Rockefeller Foundation and some of the workers from Brazil. Work began in July, and the last *Anopheles gambiae* was discovered in February, 1945. Anti-larval work was stopped six months later, and the invaded area successfully passed the test of freedom in the following year. The details of this campaign have been described by Shousha,[2] and those of a similar scheme in a small area of the Sudan by Lewis.[3] Neither of these authors gives the actual cost of the work, but it is understood that in Egypt it was high, of the same order as that in Brazil, while in the Sudan it was relatively low. These three campaigns had a marked similarity—all were against the same mosquito, which tends to choose readily discoverable breeding-places and was in each case foreign to the area and perhaps not well adapted to it, and no attempt was made to eradicate indigenous species. An even more important similarity was the fact that in Brazil and Egypt there was a feeling of impending national calamity which made the operation similar to a war campaign, to be backed with all national resources without limit.

In 1946 the Government of Cyprus decided to attempt the eradication of all species of anophelines in the island as a matter of normal policy. The campaign was referred to by Professor G. Macdonald in a letter which appeared in our correspondence columns last week. The island was more malarious than either Egypt or Brazil, and was infested by seven indigenous species of anophelines, three of which were known to carry malaria. Work was begun in the face of public apathy, or even opposition, each step having to be justified on its merits. The principles of control were the same as those in Egypt and Brazil, but a solution of D.D.T. in oil was substituted for Paris green as a larvicide and the work was carried out on a prearranged three-year schedule, the progress of which was described a few weeks ago in this *Journal* by Shelley and Aziz.[4] Some parts of the island have passed the final test of control—freedom despite cessation of anti-larval measures—but this test has yet to be applied to the areas which were treated between April, 1948, and April, 1949. It is understood that one or two positive records have recently been made, and more may be expected during the remainder of this year; but this should not undermine faith in the success of this more ambitious scheme, which has been carried out at a much lower cost—a sum not exceeding £310,000, or 14s. per head of the population. As with other territories, the risk of re-invasion has to be guarded against, and the fact that it has actually happened in the vicinity of the airport[5] during 1948 has made it clear that at the next revision of the International Conventions for Aerial Navigation some further provision for the disinsectization of aircraft must be made.
